son and co-workers [55] observed the absorption spectra of $\text{I}^-\cdot(\text{H}_2\text{O})_n$ ($n = 0-4$) by monitoring photofragments after excitation of mass-selected ions. Among the three photodecomposition channels in Eq. 3, only electron detachment (Eq. 3c) has been observed for all the $n = 1-4$ clusters. The observed photodetachment spectra reveal that onsets of absorption are gradually blue shifted as the cluster sizes become larger. The shifts are well correlated with the VDEs determined via the PE spectra of $\text{I}^-\cdot(\text{H}_2\text{O})_n$ observed by Cheshnovsky and co-workers [22]. Interestingly, the bandshape in absorption changes considerably with increasing degree of hydration. The bare I^- spectrum shows a sharp onset at the threshold energy for $\text{I}^- \rightarrow \text{I}(^2\text{P}_{3/2}) + \text{e}^-$, and the cross-section remains almost constant once it has risen to the threshold. This behavior is typical of direct photodetachment. The gross feature for $n = 1$ is similar to that for bare I^- , but there is a small absorption enhancement just above the VDE. The enhancement around the VDE becomes more prominent for larger n , and the step-like absorption turns to a band with a distinct peak. The peaks for $n \geq 2$ come to be located lower in energy than the VDEs, and the difference from the VDE increases as the cluster size becomes larger. The absorption cross-section also increases with n . Strikingly, the small cluster with only four solvent molecules already has $\sim 70\%$ of the peak intensity of the band in aqueous I^- solution. In short, absorption bands of the hydrated I^- clusters are rapidly approaching the bulk CTTS band with respect to both shape and intensity.

The above-mentioned change in absorption for $\text{I}^-\cdot(\text{H}_2\text{O})_n$ ($n = 0-4$) demonstrates the evolution of diffuse excited states supported by the solvent networks. A schematic energy diagram is illustrated in Figure 5. The slight absorption enhance-

Figure 5. Schematic energy diagram for photoexcitation into CTTS precursor states in $\text{I}^-\cdot(\text{water})_n$ clusters. Abs and VDE represent CTTS-type absorption and vertical detachment energy from the anion ground state, respectively.

ment in the monohydrate is considered as resonance in the detachment continuum, which is due to a long-range attractive potential originating from the electrostatic field by the neutral solvent. Since the dipole moment of H_2O is not very large (1.9 D), it can only support the *virtual* dipole-bound state. For the larger clusters, the dipole-bound states become stabilized below the detachment threshold. This has been rationalized by *ab initio* calculations on the ground-state anion geometry [58–60]. The most stable anions have been predicted to have a so-called ‘surface’ structure, in which water molecules are hydrogen-bonded each other with their dangling hydrogens pointing to the I^- ion. The net solvent dipole moments in the clusters (3.2, 3.5 and 4.4 D for $n = 2, 3$ and 4, respectively) are larger than the critical value (~ 2.5 D) to support a dipole-bound state [32]. Recently, the ‘surface’ structures for $n = 1\text{--}3$ have been confirmed by the results of vibrational predissociation spectroscopy [61]. The increasing dipole moments for the larger clusters are well correlated with increasing stabilization of the dipole-bound state relative to electron detachment. The resultant enhancement in localization of the diffuse orbital should provide a larger transition moment to the excited state, which is consistent with the observed increase in absorption intensity. It has been noted that the solvent orientations in the anion and neutral states should be very different each other for the larger clusters, since the estimated *adiabatic* detachment energies (ADEs) are much smaller than the VDEs. Thus excitation into the dipole-bound states produces vibrationally hot dipole-bound clusters according to the Franck–Condon (FC) principle, and the excess electron is eventually ejected, as its binding in the excited states is much weaker than the hydrogen bonding between the solvents and the I atom.

Following the above-mentioned spectroscopic study by Johnson and co-workers [55], Neumark and co-workers [56] explored the ultrafast real-time dynamics that occur after excitation into the CTTS precursor states of $\text{I}^-(\text{water})_n$ ($n = 4\text{--}6$) by applying a recently developed novel method with ultimate time resolution, i.e., femtosecond photoelectron spectroscopy (FPES). In anion FPES, a size-selected anion is electronically excited with a femtosecond laser pulse (the *pump*), and a second femtosecond laser pulse (the *probe*) induces photodetachment of the excess electron, the kinetic energy of which is determined. The time-ordered series of the resultant PE spectra represents the time evolution of the anion excited state projected on to the neutral ground state. In the study of $\text{I}^-(\text{water})_n$, 263 nm (4.71 eV) and 790 nm (1.57 eV) pulses of ~ 100 fs duration were used as pump and probe pulses, respectively. The pump pulse is resonant with the CTTS bands for all the clusters examined.

The results for FPES on $\text{I}^-(\text{water})_n$ have shown that the dynamic behavior changes substantially on going from $n = 4$ to 5 and 6. For $\text{I}^-(\text{D}_2\text{O})_4$, the relatively sharp (~ 0.3 eV, FWHM) band rises to a maximum during the first 200 fs with the electron kinetic energy (eKE) centered at 1.38 eV. Subsequently, it becomes weaker to some extent at longer times ($\sim 20\%$ after 2 ps), with its position and shape essentially unchanged. The band for $\text{I}^-(\text{D}_2\text{O})_5$ remains constant (centered at 1.38 eV eKE) during ~ 200 fs, then becomes shifted to lower eKE by ~ 0.2 eV with a time constant of 390 fs. The intensity of the PE signal starts to increase after the initial period, reaching a maximum at around 2 ps, and then slowly decreases with a decay

constant of 37 ps. The width of the spectrum also increases slightly (from 0.27 to 0.34 eV) along with the band shift and intensity increase. The gross features of the PE spectrum of $\text{I}^{\cdot-}(\text{D}_2\text{O})_6$ are similar to those of $\text{I}^{\cdot-}(\text{D}_2\text{O})_5$, with the exceptions of a change in the center eKE (from 1.33 to 1.05 eV) and the time constants of the fast band shift (560 fs) and slow intensity decay (96 ps). Isotopic substitution from D_2O to H_2O has also been examined, and all the hydrated clusters are shifted by 20 meV to higher eKE relative to the corresponding deuterated species, owing to the zero-point energy difference. The $n = 4$ clusters shows no other difference, whereas the band shifts for $n = 5$ and 6 start earlier by ~ 100 fs and the time constant of the band shift is slightly smaller for $\text{I}^{\cdot-}(\text{H}_2\text{O})_6$ (470 fs).

For the $n = 4$ cluster, the small (0.19 eV) VDE from the excited state, i.e., difference between the probe photon energy and eKE, and the relatively sharp band width confirmed that the excited state is of ‘dipole-bound’ type, which is supported by the large net dipole moment for the solvent network, as a dipole-bound state is in general located slightly below the detachment threshold and its potential energy surface is similar to that of the neutral, giving almost diagonal FC activity [32]. Therefore, the time evolution in the PE spectrum for $n = 4$ is well ascribed to the population change of the dipole-bound excited state. Because the pump photon energy is larger than the estimated ADE (4.36 eV), dipole-bound clusters generated by the pump pulse excitation are vibrationally hot. The slow decrease of the PE signal on the picosecond time-scale corresponds to a pure population decay via vibrational autodetachment.

The time evolution for the $n = 5$ and 6 clusters shows more elaborate dynamics than the population change of the excited state. The schematic energy level diagram is presented in Figure 6. Because the early-time PE spectra are similar to that for $n = 4$ in location and width, the initially prepared state is considered to be a dipole-

Figure 6. Schematic diagram of femtosecond photoelectron spectroscopy of $\text{I}^{\cdot-}(\text{water})_n$ clusters.

bound state, in which the excess electron is in a diffuse orbital extending over the solvent network. The shifts of the PE signals toward lower eKE indicate that the electron binding becomes stronger on a time-scale of several hundred femtoseconds. This stabilization should be accompanied by a substantial change in the electronic character, as the intensity gain in the PE signals is certainly due to the increase in the photodetachment cross-section. These facts have been interpreted by invoking isomerization into a more stable conformer, in which the hydrogen-bond network of the solvent water molecules is rearranged to make a more stable trapping site for the excess electron. The trapped electron after isomerization is much more localized than that in the initial dipole-bound state, resulting in a change in detachment cross-sections. The observed isotopic effects also support the structural rearrangement. The fact that the eKE shifts in $\text{I}^{\cdot-}(\text{H}_2\text{O})_5$ and $\text{I}^{\cdot-}(\text{H}_2\text{O})_6$ start earlier than in the corresponding deuterated species indicates that isomerization takes place more rapidly in the hydrated species, and strongly implies that the librational motions of the solvents must be involved in the structural rearrangement to stabilize the excess electron.

A possible isomerization pathway for the $n = 6$ cluster has been proposed on the basis of the quantum chemical calculations of Conbariza et al. [59] and Kim et al. [33]. In the predicted most stable structure for the ground state [59], the I^- ion lies on the surface of a V-shaped solvent network. It has been assumed that the initially excited state has a similar geometry, in which the excess electron is weakly bound by the net dipole moment of the solvent network. The supposed form after isomerization resembles the stable ‘half-cage’ structure for the water hexamer anion [33], in which the excess electron is confined by dangling hydrogens of waters.

Neumark and co-workers [56] pointed out the similarity of the cluster results to the transient behavior in aqueous I^- solution, which has been studied via ultrafast pump–probe measurements [50]. Bradforth and co-workers [50] observed IR (800 nm) transient absorption after UV (255 nm) excitation with 50 fs time resolution. In I^- solution, a promptly arising transient disappears within ~ 50 fs, and absorption due to solvated electron rises with a ~ 200 fs time constant. For longer time-scales, the trapped electron shows a biexponential decay with time constants of 8 and 60 ps, which is due to recombination with the nearby iodine atom. The close resemblance of time-scales for the rise of the solvated electron and isomerization in $\text{I}^{\cdot-}(\text{water})_n$ ($n = 5$ and 6) implies that the electron trapping pathway in solution can be modeled as a rearrangement of the solvent hydrogen-bond network in gas-phase clusters.

5.3.3 Dipole-bound Excited State in $\text{I}^{\cdot-}(\text{Xe})_n$ Clusters

Unlike molecular solvents, charge–dipole interaction cannot be expected between closed-shell atoms and excess electrons. However, finite and infinite ensembles of rare-gas atoms can support a bound and/or quasi-bound state for electrons, due solely to the collective polarization of the surrounding atoms. In bulk Xe, for instance, the conduction band lies ~ 0.7 eV below the vacuum level [62]. The formation of negatively charged clusters has also been reported for He [35–37], Ne [38]

and Xe [39]. This has promoted the idea that clusters of stable anions, e.g., I^- , solvated with a sufficient number of rare-gas atoms can support a diffuse excited state, in which the excess electron is essentially transferred to the solvent moiety, such as polar molecular solvents mentioned above. This idea was confirmed by the study of I^- clusters solvated with a number of Xe atoms, the polarizability of which is fairly large.

Cheshnovsky and co-workers [57] characterized diffuse excited states in $\text{I}^-(\text{Xe})_n$ ($n = 1-54$) via PES and photofragment action spectroscopy. It was noted that the $n = 12$ cluster predominates in the mass spectrum, i.e., $n = 12$ is a 'magic number'. This implies that the cluster has an icosahedral structure in which the first solvent shell becomes closed. All the PE spectra measured with excitation by ~ 5 eV photons indicate two Gaussian-like bands with an ~ 1 eV interval. The band lower in binding energy corresponds to the detachment to $\text{I}(^2\text{P}_{3/2})$, and the higher energy band to $\text{I}(^2\text{P}_{1/2})$. The VDEs for both channels gradually increase with increasing cluster size: from 3.06 to 3.96 eV ($^2\text{P}_{3/2}$) and from 4.01 to 4.90 eV ($^2\text{P}_{1/2}$) from $n = 0$ to 54. The VDE indicates an almost linear dependence on n for $n = 0-12$, then the slope suddenly becomes smaller for $n \geq 12$. This abrupt change is consistent with the first solvent shell closure.

Examination of the photodecomposition products revealed that electron emission is the only discernible channel after photoexcitation around the VDEs. The size evolution of action spectra for smaller clusters ($n = 0-12$) is similar to that which appears in $\text{I}^-(\text{H}_2\text{O})_n$ ($n = 0-4$). The step-like spectrum of bare I^- shows an enhancement around the VDE to the $^2\text{P}_{3/2}$ channel, which becomes narrower to form a distinct band as n increases. The absolute peak position in absorption becomes higher in parallel with the VDE, but the peak shifts toward lower energies relative to VDE with larger size. Therefore, the absorption peak lies above the VDE for $n = 0-3$ and becomes lower for $n \geq 4$. The relative absorption cross-section increases gradually by about two orders of magnitude from $n = 1$ to 12. In the vicinity of the VDE ($^2\text{P}_{1/2}$), a small peak with a relatively narrow width appears at $n = 4$, and it becomes stronger and lower in energy relative to the VDE as n increases. The energy shift of the band peak from the VDE is the same for the $^2\text{P}_{3/2}$ channel within the experimental accuracy. All the observations are well ascribed to a gradual stabilization of a diffuse excited state by the increasing polarization of the Xe solvent shell. The crossover from a quasi-bound excited state to a bound state takes place at $n = 4$. This critical size is consistent with the observation that a pure Xe cluster as small as $n = 6$ can support a stable anionic form [39].

For clusters with $n \geq 13$, the action spectra show a drastic change, i.e., the lower energy band correlating to the $^2\text{P}_{3/2}$ channel disappears almost completely, while the upper band to the $^2\text{P}_{1/2}$ channel appears for all the clusters as in the cases with $n \leq 12$. Because the bound state to the $^2\text{P}_{3/2}$ channel is gradually stabilized for $n \leq 12$, it must exist below the VDE for larger clusters. The disappearance in the action spectrum should be attributed to inefficiency in electron emission after excitation into the bound state. This was proved by performing two-photon action spectroscopy (2PAS), in which a UV pulse excited the cluster into the $^2\text{P}_{3/2}$ band and the second near-IR light pulse induced the electron detachment. The $^2\text{P}_{3/2}$ bands for $n \geq 13$ have been observed clearly by 2PAS, and it has been confirmed that the excited bound state is regularly stabilized in the whole range of cluster sizes examined.

The inefficient electron emission from the $^2P_{3/2}$ band for the larger clusters has been explained in terms of temperature which depends on the cluster size. Excitation above the $VDE(^2P_{3/2})$ can be followed by autodetachment via direct coupling with the electron continuum to form $e^- + I(^2P_{3/2})$. However, electron ejection after excitation below the $VDE(^2P_{3/2})$ needs additional vibrational energy, which is converted through non-adiabatic relaxation to electronic energy to overcome the electron binding. Vibrational excitation in the excited state is achieved with off-diagonal FC activity in electronic transitions, or simply transferred from vibrationally hot clusters in the ground state. Considering the narrow bandwidth in absorption, the latter is more probable for $I^-(Xe)_n$. Hence the $^2P_{3/2}$ absorption band appearing in the action spectra are due mainly to vibrationally hot ground-state clusters. It has been considered that the temperature of a cluster ensemble with definite size is determined by evaporative cooling [63]. Since binding between the I^- core and Xe atoms in the first solvent shell is fairly strong, evaporation in the clusters with $n = 1-12$ is not so active, resulting in a higher temperature. On the other hand, binding for second-shell Xe atoms is estimated as less than half that for the first-shell atoms, and therefore the temperature for the larger clusters is much lower owing to efficient evaporation. This is consistent with the abrupt disappearance of the $^2P_{3/2}$ band in the action spectra.

5.4 Electron-transfer Reactions in Large Donor–Acceptor Molecules Studied Under Jet-cooled Conditions

Studies on electron donor–acceptor (EDA) molecules in condensed phases have a long history. Since the EDA interaction was first proposed by Mulliken [64], an appreciable number of reviews on this subject have been published during the latter half of the 20th century [65]. Similar studies under isolated jet-cooled conditions started in the 1980s and have supplied detailed information on the static and dynamic characters of excited electronic states responsible for the electron transfer [66]. The present section does not intend to cover all the details of the EDA studies in jet-cooled conditions but rather focuses on selected EDA molecules consisting of anthracene derivatives. Although limited in scope, the subject provides the most essential aspects of the EDA phenomena observed in an isolated system or in solvated clusters.

EDA molecules consist of the donor and acceptor parts within a single molecular frame. N,N' -Dialkylaniline constitutes the most familiar donor part and anthracene is the most frequently used acceptor part. Anthracene can also be used as a donor moiety. A group of molecules where the donor and acceptor parts are separated by a saturated hydrocarbon chain $-(CH_2)_n-$ as in Figure 7 are called *bridged* EDA molecules. All the EDA molecules composed of anthryl and dimethylanilino moieties were reported to form a charge-transfer (CT) state in polar liquid solvents [67]. In isolated jet-cooled conditions, however, only the specific bridged EDA molecules can form the CT state. To enable the other bridged EDA molecules to form the CT state, at least one polar solvent molecule should be attached to the parent EDA molecule.

Figure 7. Typical EDA molecules with anthryl moieties.

In the present section, we first describe the details of the intramolecular charge-transfer (ICT) state formation in several directly connected (i.e., $n = 0$) EDA molecules from our recent studies, and then review the reported features of the bridged EDA molecules.

5.4.1 Directly Connected EDA Molecules

9,9'-Bianthryl

In 9,9'-bianthryl (BA) shown in Figure 7, the anthryl moiety acts as both a donor and an acceptor. On photoexcitation in a polar solvent, BA forms the ICT state via the ordinary S_1 state or so-called locally excited (LE) state. Although CT state for-

Figure 8. Dispersed fluorescence spectra of free BA, 1:1 BA-Ar and 1:1 BA-H₂O complexes. The 1:1 BA-H₂O complex shows red-shifted CT emission whereas the BA-Ar complex gives fluorescence from the vibrationally relaxed LE state.

mation in polar liquid solvents has been extensively studied for many decades [68], the precise determination of the torsional potential around the 9,9'-bond became possible only about 10 years ago with the combined use of jet cooling and laser excitation [69–71]. The torsional potential was found to be seriously affected by an attached solvent atom or molecule [72]. A water molecule, as a polar solvent, enables a BA molecule to form the CT state by stabilizing the polar state. The fluorescence of the 1:1 BA-H₂O complex is considerably red shifted as in Figure 8 and shows a long lifetime which is characteristic of the intramolecular CT state [73].

The time dependence of the fluorescence at several wavelengths is illustrated in Figure 9. The resonance fluorescence at the excitation wavelength, 375 nm, dies away within 20 ps while the fluorescence at 380 nm rises with the same time con-

Figure 9. Time-resolved fluorescence of the 1:1 BA-H₂O complex at selected wavelengths after the excitation at 375 nm. The rapid decay of the resonance fluorescence at 375 nm coincides with the fluorescence increase at 380 nm, which then decays with a time constant of 50 ps. The CT emission from the equilibrated state at >400 nm grows simultaneously with the decay of the 380 nm emission.

stant. As the latter fluorescence decays, the CT fluorescence at longer wavelength (>400 nm) appears with the common time constant of 50 ps. Such features suggest the simultaneous occurrence of CT state formation and intramolecular vibrational-energy redistribution (IVR). The IVR in the LE state and the formation of the CT state may take place within 20 ps and the 380 nm fluorescence probably comes from the highly vibrationally excited CT state, which eventually relaxes to the vibrationally equilibrated CT state. This equilibrated CT state emits the ordinary red-shifted CT fluorescence [73].

The structure of the 1:1 BA-H₂O complex in its ground state has been determined by rotational coherence spectroscopy (RCS) using the fluorescence depletion scheme [74, 75]. The empirical minimum-energy calculation supplemented the insufficient information obtained from the RCS measurement [74]. In the structure giving the best fit to the RCS signal, the water molecule sits on the terminal aromatic ring of the one anthracene moiety. Thus the two anthracene moieties are stabilized by the water molecule in a different manner, and such asymmetry in the stabilization, i.e., symmetry breaking, facilitates the electron jump from one anthracene to the other [76].

4-(9-Anthryl)-aniline and 4-(9-anthryl)-*N,N'*-dimethylaniline

The second typical EDA molecule is 4-(9-anthryl)-*N,N'*-dimethylaniline (ADMA), where the anthracene acts as an acceptor and directly links to dimethylaniline, the donor. Studies in the condensed phase revealed that ADMA and BA offered a sharp contrast in their dynamic behaviors of ICT state formation [77–80]. The dy-

namics of BA can be analyzed simply in terms of the two-state model including only the LE and CT states. In contrast, the dynamics of ADMA are complex. One has to assume many intermediate states between the LE and the CT states. This contrasting behavior probably originates from the difference in their torsional potentials in both the ground and excited states. However, the precise determination of the torsional potential of ADMA is difficult because of the significant complexity of the vibrational features appearing in the LIF spectrum [81]. We then synthesized 4-(9-anthryl)-aniline (AA), which possessed only one internal rotor, and demonstrated that the LIF spectrum became much simpler than that of ADMA to facilitate the estimation of the torsional potential [82–85].

The characteristic features of the CT formation dynamics in AA proved similar to those of ADMA [83]. The detailed analysis of the vibrational structure revealed the presence of a new low-lying CT state in addition to the LE state [84]. Taking account of a coupling between this CT state and the LE state, we successfully reproduced the spectra and evaluated the torsional potentials of the ground, the LE and the CT states, as shown in Figure 10. In an isolated AA molecule, the CT state is non-perpendicular and charge separation is incomplete. The presence of the NH_2 substituent is responsible for the low-lying CT state while the flexibility in torsional

Figure 10. Ground- and excited-state torsional potentials of AA. In addition to the ordinary LE state, a new low-lying excited state with partial CT character exists in the vicinity of the LE state.

motion yields the non-perpendicular CT state. These findings are the key to understanding the so-called multistate CT in ADMA and its homologs.

The effect of microscopic solvation on the electronically excited states of AA was then studied by using solvated clusters of AA produced in a free jet [85]. The magnitude of the red shift and the broadness in the dispersed fluorescence spectra depended on the solvent polarity and the clustering number. Both the low-lying partial CT state and the ordinary full CT state are involved as the fluorescing state, and their relative contributions depend on the polarity and the number of solvent molecules.

5.4.2 Bridged EDA Molecules

In the bridged EDA molecule **I** (Figure 7) where the donor dimethylaniline and the acceptor anthracene are bridged by a saturated hydrocarbon chain $-(CH_2)_n-$, the features of the electron-transfer reaction are known to be strongly dependent on the chain length n . Mataga and co-workers demonstrated that in the condensed phase bridged EDA molecules with $n = 0, 1$ and 2 formed the CT state only in polar solvents. In the case of $n = 3$, the CT state was formed even in non-polar solvents [86]. The rise time of the CT emission in 2-propanol was 54 and 93 ps for $n = 1$ and 2 , respectively. In n -hexane solvent, a rise time of 2.6 ns was reported for the $n = 3$ molecule.

Zewail and co-workers first observed the behavior of the CT formation for the $n = 3$ bridged EDA molecule in isolated jet-cooled conditions [87, 88]. They found that the rate of electron transfer depends on the excess energy given to the EDA molecule and not on the vibrational mode to be excited. This implies that the IVR in the LE state precedes the CT reaction. They confirmed this mechanism by demonstrating that an RRKM calculation could reproduce the energy dependence of the CT rate. The IVR accelerates the structural change, i.e., folding, of the EDA molecule in the LE state so that the donor part most favorably overlaps the acceptor part.

Levy and co-workers showed that the similar bridged EDA molecule **II** (Figure 7) in isolated conditions gave CT fluorescence only for $n = 2$ (actually $n = 3$ when including the N atom) and one isomer of $n = 4$ [89]. This finding again indicates the essential role of the overlap between the donor and acceptor parts. Verhoeven and co-workers then demonstrated that, even in the rigidly bridged EDA molecule **III** where the donor and acceptor are apart by 6.7 Å, CT could occur as a result of the chair-boat isomerization [90, 91]. They assumed the existence of an extended CT state which is produced by a rapid electron jump in the chair form. This extended CT state then isomerizes to the boat form CT state with the aid of Coulomb interaction between the donor and the acceptor just like in the harpooning scheme. They also showed that the CT rate depends on the given total excess vibrational energy in the LE state.

In summary, for bridged EDA molecules in isolated jet-cooled conditions, folding is essential for the electron transfer to intensify the overlap between the donor and acceptor. In the condensed phase, a polar solvent assists the electron transfer even for molecules which cannot form a folded structure. The 1:1 bianthryl-H₂O

complex provides such an example of 'solvent-assisted electron transfer' in isolated conditions.

5.5 Conclusion and Outlook

In the first two parts of this chapter, electron transfer (ET) from atomic donors, e.g., alkali metals or the iodine anion, to an accepting unit composed of simple molecular or atomic solvents was discussed. It was demonstrated that even for a molecule without a stable anionic state or large dipole moment, e.g., water and ammonia, an ensemble of a relatively small number of the molecules can act as an electron acceptor. In the case of the solvated alkali metal atom clusters, ET takes place spontaneously as the number of solvent molecules increases, while the ET in the solvated I^- clusters is induced by photoexcitation into the diffuse electronic excited states just below the vertical detachment thresholds. These ET processes in isolated supermolecular systems resemble the charge delocalization phenomena in condensed phases, e.g., excess-electron ejection from alkali metals into polar solvents and the charge transfer to solvent in a solution of stable anions.

The key feature which has allowed remarkable advances in studies of the ET in these supermolecular systems is close agreement of experiment and theory. Detailed comparison of the results from photoabsorption and photoelectron spectroscopy with molecular orbital calculations has revealed the stepwise evolution of the excess-electron distribution after the ET. Such an intimate interplay between theoretical and experimental work will certainly be enhanced in the future to gain more discerning insights into the ET processes in isolated supermolecules. At present, information on the solvation structure is mainly derived from quantum-mechanical or empirical-model calculations. It is highly desirable that the experimental methods for definite structural characterization, e.g., spectroscopy with vibrational and/or rotational resolution, be applied more extensively to various systems that execute ET to solvent networks. Time-resolved experiments utilizing ultrafast laser facilities are another promising direction for exploring dynamic aspects of the ET in supermolecules. Owing to the recent advances in ultrafast laser technology, real-time ET dynamics in condensed media can be probed in great detail. Comparison of the two closely related systems should be fruitful, although the results derived from one cannot simply be transferred to the other.

In the last part of this chapter, intramolecular charge transfer (ICT) in anthryl derivatives with linked donor–acceptor parts was discussed. Ultrafast spectroscopy has been applied both for structural characterization and for real-time probing of the ICT in this case. Microscopic solvation effects on the torsional motions and the ICT in the molecules have been examined by the use of their clusters with polar solvents. One of the most important problems which awaits for further studies is an ambiguous description of the electronic character of the charge-separated states in the systems. So far, high-level quantum-mechanical calculations have not been able to deal with such large molecular systems, but reliable evaluation of electronically

excited states in these molecules will soon be achieved thanks to the rapid progress in computational capability. Of course, their transient nature after photoexcitation should be more thoroughly characterized experimentally, and time-resolved measurements with sufficient state selectivity, e.g., femtosecond pump–probe absorption and photoelectron spectroscopy, will be utilized in future.

Molecular-Level Electronics

1 Wires Based on Metal Complexes

Jean-Pierre Launay and Christophe Coudret

1.1 Introduction

Polymetallic complexes with suitable bridging ligands can be useful models of molecular wires. In the present chapter, we shall consider mainly bimetallic systems in which two metal atoms are connected by a bridging ligand, with the general topology shown in Figure 1.

By extension, some compounds in which the bridging ligand contains a metal unit will also be considered. The present chapter will be focused on the case of mixed-valence compounds, for which reviews covering the basic processes are already available [1, 2].

In most cases, the metal atoms are in fact end groups necessary to define a starting site and an arrival site, while the spacer is usually purely organic. The concept of a molecular wire requires something to be transferred between these two sites more efficiently than if the two sites were separated by empty space. The present chapter will deal essentially with electron (or hole) transfer, but the related topic of energy transfer (treated extensively in Part 1, Chapter 3 of this volume) will be also evoked. Representative examples of electron and energy transfer in polynuclear transition metal complexes can also be found in recent reviews by Juris, Balzani et al. [3a] and by De Cola and Belser [3b].

The distinction between the end groups and the spacer (the wire itself) is not a trivial one. It seemed to us logical to incorporate in the definition of the end groups the immediate coordination sphere, for instance the coordinated pyridine ring in the complexes of the Creutz–Taube family. Thus the spacer would be all the rest of the structure, even if it has no independent chemical existence. In a number of cases, the spacer is made of several *repeat units*, in order to allow the construction of long molecules by repetitive synthesis or even polymerization. Finally, one has to distinguish the *spacer* from the *bridge*, the latter including the coordination sites. The definition of all these terms is made clear by the example of Figure 2.

Among the numerous bimetallic complexes known in the literature, we have selected those for which the metal–metal distance exceeds a minimum value, taken

Figure 1. General topology of the complexes.

Figure 2. Nomenclature used in the present review: end groups and spacers.

as 10 Å. The metal–metal distance provides an easy way to compare structures, and the 10 Å limit selects complexes for which relatively uncommon processes may occur. Note that with the above definition, complexes with the ligand 4,4'-bipyridine would present only the end sites, but not *stricto sensu* a spacer. However, we have kept these complexes in the scope of this review, since the M–M distance is 11.3 Å, and they have been the subject of a large number of fundamental studies and tests of new methods and concepts.

1.2 Bimetallic Metal Complexes as Models of Molecular Wires

By reference to macroscopic electrical devices, the concept of a wire is fundamentally based on intramolecular electron transfer, and this will be the main focus of

Figure 3. a) Electron transfer and b) Dexter-type energy transfer.

this review. Electron transfer occurs in its simplest form in mixed-valence complexes. It is also encountered in some excited-state processes where charge separation occurs after a photochemical excitation. Energy transfer bears some analogy to electron transfer when it occurs by the Dexter mechanism [4], i.e. a double electron transfer in which an electron jumps from the LUMO of the donor to the LUMO of the acceptor, while simultaneously an electron moves from the HOMO of the acceptor to the HOMO of the donor (see Figure 3).

Why study electron transfer in bimetallic metal complexes? A first justification is that this is a fundamental and ubiquitous process occurring in diverse fields of chemistry, physics, and biology. Of particular importance is the question of the decay law of electronic interaction or electron transfer rates with distance, which is of paramount significance for biological electron transfer. Another interesting topic is the development of molecular switches (in the electrical sense of the word), i.e., molecules able to allow or block intramolecular electron transfer according to a definite perturbation. This development clearly requires the mastering of long-distance electron transfer (over 15–20 Å), because the switching unit must be inserted on the electron transfer path.

Finally, molecular wires based on metal complexes can be used as models to understand the basic processes occurring in (bulk metal)/molecule/(bulk metal) nanojunctions (Figure 4). Such nanojunctions can now be prepared by several methods: “broken junction” [5a], nanodeposition on ultrathin metallic wires [5b], deposition of a suitable molecule on atomic steps of a metallic surface [5c], etc., and they allow the measurement of an electron flux (i.e., a current) through a single molecule. In the case of bimetallic metal complexes, there is just one atom connected at each end, and just one electron moving. In addition, the bimetallic complex involves only one or a few energy levels at each end, while there is a continuum of such levels in the case of ultrathin metallic wires. However, the electron transfer involves the same general principles; in particular, in complexes as in nanojunctions, it is governed by the tunnel effect: the energy levels of the coordinated metals fall in the “gap” be-

Figure 4. a) Bimetallic metal complex, b) monometallic complex linked to a surface, and c) metal/molecule/metal nanojunction.

tween the ligand's HOMO and LUMO, and thus the situation in which one electron or hole has been transferred to the bridge is a high-energy one. The advantage of metal complexes is that they are chemically and geometrically well defined at the metal–molecule connection. Thus the study of bimetallic metal complexes could be a rapid screening procedure to identify efficient molecules or molecular fragments in order to build molecular nanojunctions.

1.3 Synthetic Strategies

The lack of systematic studies, sustained by theoretical calculations, may explain the large variety of molecular wires (as well as a very poor definition of this notion)

that can be found throughout the literature. However, the proposed syntheses can be sorted according to two general strategies:

- a “classic” strategy, in which the bridging ligand is prepared before the complexation step. This allows a large versatility, since such a ligand would be suitable for various studies including energy transfer. This strategy is appropriate for short ligands, or if the organic precursors are easily available. One of the main difficulties, apart from the handling of a chemical species with free coordination sites (i.e., basic atoms) which may not be trivial, is the final complexation step of a sophisticated and high added-value molecule.
- a “metal complex as building block” strategy in which metallic complexes are used as special organic synthons, the key step being their grafting on an organic core. This strategy is used routinely for complexes with unstable anionic ligands, the most common example being ferrocene. However, it is now applied even for non-organometallic species, especially for chiral complexes since enantiomer resolution can be achieved relatively early in the synthesis on very simple mononuclear precursors [6b]. It has been used in the case of a complex acting as bridging moiety (the “complex as ligand” approach) [7–10].

Eventually, regardless of the strategy used, a recurrent problem is the solubility of the final wire. It is known that rod-like molecules tend to aggregate, especially if they are relatively rigid. Such a problem is usually circumvented by grafting alkyl groups [11]. Another solution is to use ionic complexes, whose charge is expected to allow an efficient solvation of the molecule. However, aggregation in solution can never be ruled out [12a].

Since the synthetic reactions are intended to build the redox centers on one hand, and the conjugated spacer on the other, we have followed this order to present selected examples of syntheses.

1.3.1 Redox Centers

Since metallic ions are supposed to be the only part of the molecule where the extra electron has to reside, one has to be sure that all the interesting redox processes are metal-centered. It is usually true that most of the organic molecules display a moderate reactivity in redox reactions: a large HOMO–LUMO gap, and subsequent rearrangements, tend to decrease electron transfer rates and destabilize the oxidized (or reduced) form of the spacer—thus moving the bridge’s redox couple out of the solvent’s electroactivity window. However this is not true for unsaturated molecules, and as the length of the conjugated part increases, one has to think about redox processes involving the spacer.

Another difficulty comes from the spectroscopic technique used to probe the degree of electronic interaction, which relies basically on the observation of a metal-to-metal charge transfer band (intervalence band) in the near-infrared (NIR). A simple analysis based on the Franck–Condon principle leads to the conclusion that its shape and energy may depend on the geometry change between the reduced and

oxidized form (vide infra, Section 1.4.1 and Figure 13). Thus limiting this distortion should keep the intervalence band in the NIR region, i.e., separated from the other bands. Complexes having a rigid coordination sphere made of multidentate ligands appear promising candidates. However, other low-energy charge transfers originating from low-lying ancillary ligand π or π^* orbitals (such as LMCT), may nevertheless overlap with the intervalence band.

Chemical stability, and more precisely *kinetic* stability to avoid ligand scrambling, is needed for all the concerned oxidation degrees, not only during the redox titration but also for synthetic purpose, especially in the building block approach. The use of heavy transition metals (second or third row), known to give slow ligand exchange reactions, is helpful, but the counterpart is harsh complexation conditions. A careful choice of the ancillary ligand will also bring the interesting redox couple away from the borders of the electroactivity domain of most of the solvents. It may be also important not to populate anti-bonding orbitals (i.e., e_g for an octahedral or pseudo-octahedral geometry) of the metallic complex during the redox processes. Finally, it is more convenient from an analytical point of view (NMR identification) to work with diamagnetic complexes as primary forms. The most common redox groups are listed in Table 1.

For all the above reasons, ruthenium has become a very popular redox site: as a (relatively cheap) heavy metal, its complexes are kinetically stable and its crystal field Δ parameter value is relatively high. Hence, for most common complexes of ruthenium(II) of pseudo-octahedral geometry, the d^6 electronic configuration is a low-spin diamagnetic state, and frontier orbitals, involved in the redox processes are essentially of the nonbonding “ t_{2g} ” type. Eventually its rich photochemistry may be used to probe excited-state behaviors.

Classic strategy

Classically, the redox site are obtained by a “traditional” complexation reaction. This supposes the substitution of a labile ligand from the coordination sphere of the metallic precursor by the desired coordinating ligand. Among the most common, we can find neutral sites made of basic di- or trigonal nitrogens (nitriles, heterocycles), or anionic sites usually based on heteroatoms, digonal or trigonal carbides (acetylides, σ - or π -aryl). Chelation, and especially for heavy metals changes in the degree of oxidation of the metal, enhance the reaction rate. Labile ligands of the metallic precursors are usually halide or solvent [13], and sometimes nitrosyl [14a]. Several examples are shown in Figure 5.

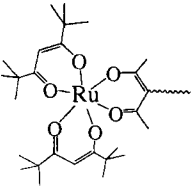

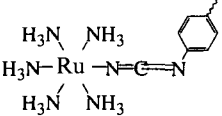

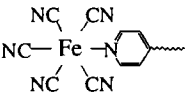

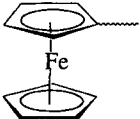

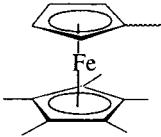

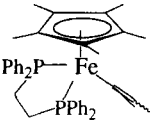

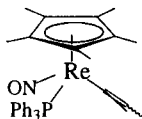

“Metal complexes as building blocks” strategy

In some cases, it is more convenient to handle a complexed ligand rather than a free one. This is especially true for organometallic complexes since free and complexed ligands may have a totally different chemistry. The latter point can be used to achieve easily a functionalization which would be tedious with the free species [11, 17b, 18, 22]. When the latter is impossible (the complex is destroyed during functionalization, or no special activation is gained by complexation), the alternative

^acharges are omitted for clarity.

route is to use “prefunctionalized ligands” [6, 17b, 26a]. Examples of the “building blocks” strategy are given in Figure 6.

The other aims of such a strategy are: (i) to maintain fairly good solubility of the growing wire, and (ii) especially for heavy metals, to avoid submitting the final wire, usually a very conjugated hence fragile molecule, to complexation conditions.

On the other hand, most of the disadvantages come from the fact that the free

Figure 5. Examples of redox site syntheses, with literature references in bold.

Figure 6. Some metal complexes used as building blocks, with literature references in bold.

ligand remains unknown, and, because of the “hybrid” nature of this “metallo-synthon” (a term coined by Ziessel) [26a] the adaptation of the reaction conditions (i.e., solvents, use of strong bases, etc.) is sometimes difficult.

1.3.2 Conjugated Bridges

Molecular wires may be considered as a special case of conjugated and rigid rod-like molecules. A recent review by Michl and co-workers [27] gives an exhaustive view of this field, and our purpose here is only to give additional clues in order to appreciate the synthetic choices.

Figure 7. Examples of oxidative couplings.

Traditionally, the very unsaturated bridges can be viewed as an alternation of conjugated units (triple bond, double bond, aromatic nucleus ...) and simple bonds. In most of the strategies, the synthetic effort is focused on the creation of these simple bonds by redox dimerizations, or metal-catalyzed cross-couplings. In some cases, especially for double bonds, it is the unsaturated unit which will be the target of the synthesis. This is usually achieved by a condensation reaction (with the important exception of the McMurry reaction [28]). Other routes to polyunsaturated systems do exist, but they may have not been used yet to build bridging ligands or they are too marginal; hence our list is certainly not exhaustive.

Redox dimerizations

Such reactions are used to prepare bridging ligands having one main symmetry element (mirror plane or C_2 axis) passing between two (carbon-) bonded atoms. Except for some metal-catalyzed reactions, redox dimerizations are generally interpreted as the recombination of two radical species—followed, if needed, by a dehydrogenation step—hence generating a simple bond.

Oxidative dimerizations (see Figure 7)

Controlled oxidation of organometallic species may lead to the creation of a C–C bond. In acetylene chemistry, the Glaser reaction and its variations [29] are among the most ancient reactions of this type, and rely on the oxidation by air (or cupric ions) of alkynyl copper(I) species generated in situ. These very mild conditions allow the use of a large range of terminal alkynes, such as ethynylated heterocycles (Figure 7a) [26b].

Biaryls can also be obtained by oxidation of arenes, as long as these are electron-rich enough. Some very short dinuclear complexes have been obtained in this way. Thus, a bis-cyclometallated dinuclear complex has been obtained by a smooth oxidation of a nonfunctionalized precursor by silver(I) ions (Figure 7b) [17a].

Figure 8. Examples of reductive couplings.

Reductive dimerizations (see Figure 8)

A radical species may also be generated by reduction of an electron-deficient compound and a classical entry to 4,4'-bipyridines is the reduction of a pyridine by sodium and subsequent rearomatization. Figure 8a illustrates the use of such a reduction in order to prepare the precursor of a sodium-ion molecular switch [30].

A more general route, derived from the ancient copper-catalyzed Ullmann coupling, is the metal-induced dimerization of an aryl halide. The key step is a reductive elimination within the coordination sphere of the metal. A nickel(0) complex, in stoichiometric quantities, is usually selected for this purpose. Constable and Ward have used such a reaction to prepare a bis-terpyridine from an interesting synthon, which would have otherwise required a more specialized strategy with dedicated intermediates (Figure 8b) [31].

Condensations

Examples are shown in Figure 9. Reactions between an active methylene compound and a ketone or an aldehyde are an attractive entry to double bonds, as long as one can control the final stereochemistry. Among them, the Wittig–Horner reaction, requiring relatively mild reaction conditions (i.e., a strong base), gives excellent results and has been used successfully by Lehn [32] and Ziessel [33] to introduce coordinating sites, respectively a bipyridine, or a terpyridine (Figure 9a) unit on a carotenoid. The reaction, under thermodynamic control, produces only the *trans*-isomer with no isomerization of the other double bonds. A similar approach was used to prepare oligo(phenylene-vinylene) bridging ferrocenyl units (Figure 9b) [11].

The condensation between a carbonyl and an amine leads to the rather fragile imine link. However, its stability is greatly increased when it is included in a heterocycle. This may be used to prepare “ladder molecules” such as polyquinoxalines.

**Figure 9.** Examples of condensation reactions.

Thus, the reaction between a diamino building block and tetraketopyrene gives a dinuclear complex with a metal–metal distance of 20 Å (Figure 9c) [12].

Metal-catalyzed hetero cross-couplings

Recent developments in the chemistry of polyunsaturated compounds are due to an extensive use of metals as catalysts to create single bonds between sp - or sp^2 -hybridized carbon centers. At first copper, and now palladium and nickel, are routinely used in such reactions, which may be viewed as a formal nucleophilic displacement of an electronegative substituent, denoted X, i.e., a halogen, by an organometallic species, denoted Rm. For transition metal catalysts (Pd, Ni), the catalytic cycle involves an oxidative addition of the “electrophilic moiety”, i.e., the organic halide RX, on the most reduced form of the catalyst, followed by a transmetalation step with the “nucleophilic moiety” Rm, leading to a complex containing two formally carbanionic ligands. Such a complex is unstable and evolves through a reductive elimination process to a reduced form of the catalyst, and the desired cross-coupled compound. (In the Heck reaction, the “nucleophilic moiety” is an alkene: hence coupling goes through successive *cis*-migration and β -elimination reactions).

Rate-determining steps are usually the oxidative addition (the more electron-deficient the RX, the faster the addition), and/or the transmetalation of Rm to palladium.

Copper

In order to prepare nonsymmetrical diynes, one can use the Cadiot–Chodkiewicz reaction. It involves a haloalkyne such as an iodoalkyne or a bromoalkyne. Combined with the Glaser dimerization, this reaction provides a powerful entry to oligoynes bridging ligands and has been used extensively by Gladysz (see Figure 10) [34].

Palladium

Excellent reviews on the use of this metal as catalyst in cross-coupling reactions are now available [35]. The mild reaction conditions, as well as the wide scope of compatible functionalities, characterize palladium couplings, leading to a considerable simplification of the retrosyntheses—hence its increasing popularity. Examples are shown in Figure 11. Among the most common skeletons encountered in molecular wires, we have selected two representative examples now easily available by palladium chemistry: tolanses and biaryls.

Figure 10. Synthesis of poly-yne bridges [34].

**Figure 11.** Examples of palladium-catalyzed couplings.

Tolanes

An alternation of triple bonds and aromatic nuclei, “polytolane”, is easily achieved by the Hagihara–Sonogashira coupling of a terminal (poly)alkyne and an aromatic (poly)halide, combined, if needed, with a suitable sequence of alkyne protection and deprotection. Reaction conditions involve a mixture of a cuprous salt and a palladium(II) or (0) complex, and a necessary base, usually an amine. Yields are usually high, especially for aryl iodides (Figure 11a) or electron-deficient heteroaryl bromides [6]. If the reaction is too slow, alkyne degradation may be prevented by an in-situ deprotection, hence releasing the reagent at a very low rate (Figure 11b) [18].

Biaryls

Replacing the terminal alkyne by an arylzinc, an aryltin, or an arylboron compound leads respectively to the Negishi, Stille, or Suzuki aromatic cross-coupling reactions. There is no need for a cocatalyst, but the Suzuki reaction requires a nucleophilic base such as aqueous carbonate (Figure 11c) (or fluoride) [17b, 22].

Other bridges

Some architectures require specific synthesis, and we wish to focus on three other types of structures (cyanines, porphyrins, and metallic complexes) as bridging ligands (see Figure 12).

Cyanines

The conjugation of a carbanion (or a carbocation) to an even number of double bonds gives rise to a cyanine-like system, the negative (positive) charge being delocalized over an odd number of trigonal carbons. In an example reported by Tolbert (Figure 12a) [14a], a pentadienyl anionic system is used to bridge two ruthenium complexes via two pyridyl residues. The carbanion is obtained by a mere deprotonation of the twice-allylic methylene group. However, such a bridge is relatively unstable, and the conditions used for the deprotonation may destroy the metallic complexes. More recently, the same group has achieved the synthesis of the cationic counterpart bridging two ferrocenes, creating a carbocation by a hydride abstraction [14b].

Porphyrins

Very few reports are about the use of porphyrins as bridges connecting redox centers, although their annulene character may be of interest. Recently, Officer and co-workers [36] have prepared a 5,15-diferrocenylporphyrin by condensation of ferrocenecarboxaldehyde and a substituted dipyrromethane (Figure 12b). The considerable steric hindrance of the resulting macrocycle gives rise to two remarkable features: the “saddle” conformation of the porphyrin ring, as already noted for crowded porphyrins, and more surprisingly, the full conjugation of the two ferrocenyl moieties to the porphyrin ring despite their *meso* position. See Figure 12 (inset) for a sketch of the geometry.

Figure 12. Examples of a) a cyanine spacer and b) a porphyrin spacer, showing the strong distortion of the molecule in the latter case (inset).

Metal complexes

Attempts have been made to include metals within the bridge, which allow the study of new geometries, and more interestingly, the impact of the presence of an electropositive element with variously occupied d orbitals on the electron transmission. For such a goal, the most efficient strategy is to use a “metallic complex as ligand” approach, either by capping a metallic complex bearing free peripheral coordinating sites, or, since metallic ions are efficient templates, by complexing on the metallic ion two ligands bearing a redox site. The most abundant literature on this subject involves diethynyl metal complexes and relies on synthetic concepts already mentioned in this review [7–10].

1.4 Theory

1.4.1 Outline of the Theoretical Treatment of Mixed-valence Compounds

Only a brief outline will be presented here since electron transfer theory is extensively treated in Volume I. Let us just recall that electron transfer reactions are currently represented by potential energy curves of the Marcus type (Figure 13). We concentrate here on weakly coupled systems (class II according to Robin and Day’s classification) [37] for which two minima are observed on the lowest potential energy curve. (For delocalized systems (class III), it is not always clear that for long bridges, the oxidation/reduction is truly metal-centered since extensive delocalization must involve the bridge.) Returning to class II systems, the two minima are of

Figure 13. Potential energy curves for a class II mixed-valence compound.

equal height if the system is chemically symmetrical. As shown by Hush [38], there are two kinds of intramolecular electron transfer: a thermal one, and an optical one corresponding to the so-called intervalence transition (IVT) (Figure 13). A key parameter is the electronic coupling V_{ab} , also called “tunneling matrix element”, “resonance exchange integral”, “coupling element”..., which corresponds to the avoided crossing between the two zero-order parabolas. From an experimental point of view, the role of V_{ab} is twofold: 1) it allows the system to jump from one zero-order parabola to the other when arriving in the avoided crossing region, which corresponds to the thermal electron transfer process, the rate of which is proportional to V_{ab}^2 ; 2) it mixes the electronic wave functions of the ground state with that of the excited state, which determines the intensity of the intervalence transition, also proportional to V_{ab}^2 .

Since V_{ab} plays a central role in the theory, its determination in the largest possible series of compounds is of great interest. In a two-state model, a simple evaluation of the transition moment, using Mulliken’s approach of donor–acceptor systems, yields Hush’s (1967) equation [38b]:

$$V_{ab} = \frac{2.05 \times 10^{-2} \sqrt{\bar{\nu} \Delta \bar{\nu}_{1/2} \epsilon_{\max}}}{R_{MM}} \quad (1)$$

V_{ab} is obtained in cm^{-1} , ϵ_{\max} is the maximum extinction coefficient for the intervalence transition, $\bar{\nu}$ is its energy (cm^{-1}), $\Delta \bar{\nu}_{1/2}$ is its full width at half-maximum, and R_{MM} is the direct (through space) metal–metal distance. Although more than 30 years old, this equation is still widely used. A recent reinvestigation has shown in particular that its range of validity is wider than previously believed [39]. Note that for a class III system, V_{ab} is merely one-half of the optical transition energy (see Volume I).

Since the practical use of Eq. (1) requires the determination of the intervalence band for the pure mixed-valence compound, two corrections are generally applied to the experimental spectra:

a correction for the comproportionation equilibrium linking the mixed valence species with the fully reduced and fully oxidized ones:

It is easy to show that when the composition of the solution corresponds to the mixed-valence stoichiometry, the proportion P of complex present as mixed-valence form is given by:

$$P = \frac{\sqrt{K_c}}{2 + \sqrt{K_c}} \quad (3)$$

The spectrum of the equilibrium mixture can thus be corrected by subtracting the absorptions due to the fully reduced and fully oxidized forms. The K_c value

can be determined either from a redox titration [40a], or from the determination of the standard potentials of the Ox–Ox/Red–Ox and Red–Ox/Red–Red couples. This is conveniently realized by electrochemical methods such as differential pulse voltammetry [40b].

a spectral deconvolution. The intervalence band profile is very frequently polluted by the tail of more intense charge transfer (either metal-to-ligand or ligand-to-metal) transitions. The spectrum must then be decomposed as a sum of gaussian components [41].

Returning now to the comproportionation equilibrium, it is interesting to notice that for large systems ($R_{MM} \rightarrow \infty$) the comproportionation constant tends towards a statistical limit of 4 (see below). Then a single electrochemical wave is observed, a fact which has frequently dissuaded researchers from further studies on such binuclear complexes. However, even in this apparently unfavorable case, the proportion of mixed-valence species at half-oxidation (reduction) is, according to Eq. (3), a comfortable 50 %, nevertheless allowing a meaningful correction.

1.4.2 Processes Related to the V_{ab} Coupling

We now consider several phenomena or processes related to the electronic interaction. They are listed below in order of decreasing parentage with the electronic interaction defined as above.

Thermal electron transfer rate constant

This is the most direct experimental manifestation of the existence of an electronic interaction. It can occur spontaneously in mixed-valence complexes, but also in bimetallic systems after a photochemical excitation (photoinduced electron transfer). The general theory considers electron transfer as a special case of radiationless transition, with a perturbative treatment based on Fermi's Golden Rule [42]. In the nonadiabatic case, the rate constant can be written as [43]:

$$k_{et} = \frac{2V_{ab}^2}{h} \left(\frac{\pi^3}{E_\lambda kT} \right)^{1/2} \exp\left(-\frac{\Delta G^\ddagger}{RT}\right) \quad (4)$$

where E_λ is the total reorganization energy, ΔG^\ddagger is the free enthalpy of activation, and the other symbols have their usual meaning. This equation is valid for very weakly coupled systems (nonadiabatic ones), a situation which is expected to occur for long molecules. It should be noted that the rate of electron transfer in a symmetrical system such as a mixed-valence compound has rarely been determined because the thermal reaction is accompanied by no net chemical change. (For an example, but with organic end groups, see [44]). Direct measurements of the electron transfer rate constant are preferably performed by flash photolysis experiments (excited-state electron transfer).

A different experimental setup has been used in recent years to measure electron transfer rates through molecular wires. Conjugated molecules with a redox group (ferrocene) on one end and a thiol group at the other were attached to gold electrodes and embedded in monomolecular aliphatic monolayers [45]. The electrochemical response in AC voltammetry was used to measure the rate of electron transfer between the ferrocene group (accessible from the solution side of the monolayer) and the electrode. Here again, the rate depends on an electronic coupling factor V_{ab} (Eq. (5)).

$$k_{et} = \rho(E) V_{ab}^2 \left(\frac{2\pi kT}{h} \right) \sqrt{\frac{\pi}{E_\lambda kT}} \int_{-\infty}^{\infty} \exp \left[\frac{-((\varepsilon_F - \varepsilon) + E_\lambda)^2}{4E_\lambda kT} \right] f(\varepsilon) \frac{d\varepsilon}{kT} \quad (5)$$

where $\rho(E)$ is the density of states of gold near the Fermi energy, $f(\varepsilon)$ the Fermi function, ε_F the Fermi energy, and E_λ the reorganization energy.

Note the analogy between Eqs. (4) and (5): electron transfer at the interface can be considered as a special case of intramolecular electron transfer, the integration taking into account the existence of a continuum of energy levels on the electrode side. Thus the experimental setup is somewhat intermediate between a molecular mixed-valence complex in solution and a metal/molecule/metal nanojunction.

Dexter-type energy transfer rate

As mentioned above, this is an energy transfer process occurring by a double electron exchange, so that no net charge moves from one site to the other. A simple argument due to Closs et al. [46a] suggests that the rate of triplet–triplet energy transfer k_{TT} should be proportional to the products of the corresponding electron and hole transfer rates k_E and k_H :

$$k_{TT} = c k_E k_H \quad (6)$$

This relation was indeed verified experimentally in a series of organic molecules with naphthyl and biphenyl groups linked by rigid spacers. Assuming that each rate constant is proportional to the square of an electronic coupling element gives:

$$V_{TT} = c' V_E V_H \quad (7)$$

Thus the matrix coupling element for energy transfer would be proportional to the product of the coupling terms for electron and hole transfers. This was later confirmed by ab-initio calculations [46b].

Magnetic coupling

This corresponds to the existence of a dipolar coupling between magnetic ions in a homovalent bimetallic complex. The interaction is usually described by the following Hamiltonian:

$$\hat{H} = -J \hat{S}_A \hat{S}_B \quad (8)$$

where S_A and S_B are local spin operators and J is the coupling constant, positive for a ferromagnetic interaction and negative for an antiferromagnetic one. Although this process occurs in a homovalent complex, while electron transfer is studied in a mixed-valence complex, the two effects are related. One of the simplest theories is based on the use of magnetic orbitals [47] Φ_A and Φ_B , i.e., orbitals mainly localized on a metal site (A or B), but with some extension on the coordinated ligands. The magnetic coupling parameter is then given by:

$$J = J_F + J_{AF} \quad (9)$$

where J_F is the ferromagnetic contribution, and J_{AF} the antiferromagnetic one. J_F is given by

$$J_F = 2 \left\langle \Phi_A(1)\Phi_B(2) \left| \frac{1}{r_{12}} \right| \Phi_A(2)\Phi_B(1) \right\rangle \quad (10)$$

The antiferromagnetic contribution is given by:

$$J_{AF} = -2S_{AB}\Delta \quad (11)$$

where S_{AB} is the overlap integral between magnetic orbitals, and Δ is the difference in energy between the two canonic molecular orbitals obtained from Φ_A and Φ_B . To a first approximation $\Delta = 2V_{ab}$ and is proportional to S_{AB} .

Frequently J_{AF} dominates the J_F term, so that the observed coupling is antiferromagnetic. Equation (11) shows that J_{AF} is proportional to the square of the splitting between molecular orbitals, i.e., to the square of V_{ab} .

Nonlinear optical activity

In the simplest case of a donor–acceptor (D–A) molecule, the nonlinear optical activity arises from the electric-field-induced mixing of electronic states such as D–A and $D^+ - A^-$. This makes the response (polarizability) of the molecule different according to the sense of the electric field, and a second-order hyperpolarizability (β coefficient) is observed. If D and A are connected by some bridge, its role in promoting the electronic interaction will be quite similar to the bridge role in mixed-valence complexes. Metal complexes can play the role of donor or acceptor groups. Recent examples have been described with ferrocene or ruthenium(pentaammine) groups [48], but they are either monometallic or too short to be considered in this review.

Electrochemical wave splitting

In a bimetallic complex, the oxidation or reduction may occur in one or several steps. The corresponding difference in redox potentials, noted as $\Delta E_{1/2}$, is easy to determine, and is frequently used as a measure of the “electronic communication” between redox sites. However, one has to be careful before relating this parameter with the V_{ab} coupling. While V_{ab} is a *spectroscopic-like* quantity which depends only on the electronic properties of the mixed-valence species, by contrast $\Delta E_{1/2}$ is a

thermodynamic quantity depending on the properties of three species: the mixed-valence one, and the two adjacent homovalent forms. This is made clear by the relation between $\Delta E_{1/2}$ and the comproportionation constant K_c for the equilibrium:

$$F\Delta E_{1/2} = \Delta G_C = -RT \ln K_c \quad (12)$$

where F is the Faraday and ΔG_C the free enthalpy change for comproportionation.

To date, the best analysis of the factors determining K_c (and thus ΔG_C and $\Delta E_{1/2}$) is based on Sutton and Taube's work [49] considering mixed-valence complexes obtained by oxidation of a bimetallic ruthenium(II) complex. Four factors were recognized as contributing to ΔG_C : (i) a statistical factor $-RT \ln(4)$ since there are two equivalent redox sites, (ii) an electrostatic factor ΔG_E since the oxidation of the first metal site renders the second one more difficult to oxidize, owing to the repulsion between the two additional charges, (iii) a resonance factor ΔG_R coming from the mixing of the electronic ground state with the one of the redox isomer, and (iv) a synergistic factor ΔG_S . The last of these is the most mysterious but its existence appears nevertheless undoubtedly established. In the case of ruthenium complexes, it is due to the Ru(II) backbonding interaction. Once ruthenium(II) has been oxidized to ruthenium(III), the energy of the ligand π^* orbital is decreased, and its interaction with the other site in oxidation state (II) is amplified [50].

The original treatment by Sutton and Taube has later been refined by the addition of effects such as "structural distortion" [51] or "magnetic interaction" [52]. They do not seem to be as general as the others, and will not be discussed further.

Among the above factors, only ΔG_R , the resonance stabilization due to electron delocalization in the mixed-valence species, depends clearly on V_{ab} . The synergistic factor ΔG_S seems to correspond to some form of electronic interaction, but this is less clear than for ΔG_R . Unfortunately, the careful analysis of Sutton and Taube reveals that for long systems of the type considered here, the ΔG_R factor makes a minor contribution to ΔG_C . On the other hand, the electrostatic factor seems to give an important contribution to ΔG_C ($\Delta E_{1/2}$), but this is not interesting in the frame of Molecular Electronics: the electrostatic interaction is a through-space interaction influenced little or not at all by the nature of the bridging ligand (except through its effective dielectric constant). Thus it does not exhibit the strong directional selectivity required for a wire.

To be complete, one has also to consider the analysis by Kaim and co-workers [53], according to which K_c would be determined by the coefficients of the LUMO on the coordinating atoms of the ligands (in his case, nitrogen atoms of bis-chelating polyimine ligands).

It should be mentioned finally that, in a number of cases, the location of the oxidation or reduction (on the metal sites or on the bridging ligand?) has not been clearly established.

All of these considerations cast doubt on the use of $\Delta E_{1/2}$ (ΔG_C) for measuring the electronic "communication" between redox sites and the ability of the molecule to function as a wire. Regardless of its true nature, the wave splitting resembles some kind of polarization effect. It *does not correspond to a transfer process*, and has no counterpart in the usual behavior of a macroscopic wire.

1.5 Review of the Different Studies

In the following, the investigations are ranked by type of process, starting with intervalence electron transfer, which is the most direct way to determine the fundamental parameter V_{ab} . An important issue is the rate of decay with distance, and in most cases it follows, or nearly follows, an exponential law, i.e.,

$$V_{ab} = V_{ab}^0 \exp(-\gamma R) \quad (13)$$

Ideally, a good molecular wire should exhibit a strong coupling even for large distances, i.e., a low γ and a high V_{ab}^0 . A number of processes depend on the *square* of V_{ab} (cf. Eqs. (4), (5)), or the square of an analogous parameter (in the case of magnetic coupling, or Dexter energy transfer). In such cases, the observable quantity decays with a slope of 2γ .

1.5.1 Intervalence Electron Transfer

Intervalence electron transfer implies generally a symmetrical system, i.e., two chemically equivalent metal sites. The literature shows that most authors concentrate on a type of terminal redox group, rather than on a particular type of spacer. Thus in the following, the metal complexes will be listed according to their coordination sphere, with an indication of the ligand on which the spacer is attached (e.g., “py-” means that the substitution leading to the molecular wire is performed on the pyridine ligand). A number of reviews have already been devoted to the subject, in particular by Creutz (1983) [1], Crutchley (1994) [2], and Lapinte (1998) [23], the first two concentrating on coordination complexes, and the last one on organometallic complexes. Here, particular attention will be paid to *series* of complexes with spacers of various lengths, for the purpose of studying the role of distance. The through-space metal–metal distance (the one entering Hush’s equation) will be considered, unless otherwise stated.

$(\text{NH}_3)_5\text{Ru}(\text{py}-)$

The simplest complex is the association of two such end groups without a spacer, i.e., $[(\text{NH}_3)_5\text{Ru}-4,4'\text{-bipy}-\text{Ru}(\text{NH}_3)_5]^{n+}$. This is one of the most studied complexes as a representative example of a weakly coupled (class II) mixed-valence system [1]. In particular, it allowed the study of several original or intriguing effects: multiple intervalence transitions [54], contributions of high-frequency librations [55], and effects of unsymmetrical solvation [56]. This is also the longest mixed-valence complex for which electroabsorption spectroscopy (Stark effect) has been performed [57]. This experiment provided the value of the change in dipole moment ($\Delta\mu$) associated with the intervalence transition, a key parameter for testing new theories: while very large in the absolute sense (ca 28 D), the $\Delta\mu$ value is about one-half of the theoretical value for a full charge transfer over 11.3 Å.

Inserting one or several conjugated double bonds gives rise to complexes of α,ω -dipyridylpolyenes, $\text{py}-(\text{CH}=\text{CH})_n\text{-py}$, the first examples ($n = 0, 1$) being described by Sutton and Taube [49], and the longer ones ($n = 2$ to 4) by Launay, Spangler, and co-workers et al. [58] (series 1). Analysis of the intervalence transitions showed a slow decrease of the V_{ab} coupling term according to an exponential law, within the uncertainties of the measurements. For the longest systems, the intervalence transitions were increasingly ill-resolved. However, the inclusion of furan and thiophene heterocycles in place of two double bonds improved the resolution, probably for reasons of better coplanarity and rigidity. For the series of α,ω -dipyridylpolyene bridged systems, the experimental decay slope γ was found to be 0.070 \AA^{-1} .

Theoretical values of the coupling term were obtained by extracting the V_{ab} values from an Extended Hückel calculation, either by the “dimer splitting method”, or by the Effective Hamiltonian technique [59]. The order of magnitude of the coupling was satisfactorily reproduced, and the role of bond length alternation as a limiting factor in the long-distance transmission of electronic coupling was recognized.

An alternative theoretical treatment of α,ω -dipyridylpolyene complexes was proposed in 1990 by Reimers and Hush [41], in which the quantum calculation is performed at the CNDO level with an empirical adjustment of the d levels of ruthenium with respect to the bridging ligand orbitals. This calculation gave a higher decay slope of -0.13 \AA^{-1} . In more recent work, the explicit treatment of the solvent allowed reproduction of experimental coupling within 25 % of experimental data, with a decay slope of -0.127 \AA^{-1} [60].

The insertion of a triple bond was performed by Sutton and Taube [49]. Curiously the V_{ab} coupling was found to be smaller through dipyridylacetylene than through dipyridylethylene, a fact attributed to the almost free rotation of the two pyridine rings with respect to each other. This point is discussed later, however.

The insertion of a polyphenylene unit (up to two phenylenes) unfortunately gave particularly weak and ill-resolved intervalence transitions, precluding a quantitative exploitation [61].

Bridging by a cyanine-like ligand has been attempted by Tolbert [14a]: in the bis(pentaammine)ruthenium complex of 1,5-dipyridyl-1,3-pentadiene, deprotonation of the methylene group was expected to give a complex bridged by a pyridocyanine ligand, but the complex dissociated upon deprotonation. The concept is nevertheless interesting since bridges with an *odd* number of carbon atoms are expected to enhance strongly the coupling between redox centers [62] (see below).

(NH₃)₅Ru(NC⁻) and py(NH₃)₄Ru(NC⁻)

Complexes with 1,4-dicyanobenzene, 1,5-dicyanonaphthalene, 1,6-dicyanonaphthalene, 2,6-dicyanonaphthalene, and 2,7-dicyanonaphthalene as bridging ligands, prepared by Richardson and Taube [51], exceed the 10 Å limit for the metal–metal distance. Metal–metal couplings have been obtained by Hush’s formula and the bridging ligand role has been clarified with the help of INDO calculations. The coupling decreases exponentially with the total number of conjugated atoms. (Note that since the structures and composition of the ligands are markedly different, the exponential law is no longer obtained when plotting V_{ab} as a function of the through-space metal–metal distance). An alternation rule has been established, i.e., the most efficient bridges are those for which an even number of atoms separate the metal sites. However, even when restricted to ligands of this category (1,4-dicyanobenzene, 1,5-dicyanonaphthalene, 2,6-dicyanonaphthalene), the couplings are modest in comparison with other series, and decay rapidly with distance.

Trimetallic complexes built around a central ruthenium complex of *cis*-[Ru(bpy)₂(CN)₂] have been described by Bignozzi and co-workers [10]. Cyanide ligands are N-bonded to external py(NH₃)₄Ru sites. The general topology is therefore “bent”, with a metal–metal through-space distance of only 7 Å between the outer metal sites, but the sequence of atoms constituting the trimetallic complex is Ru–NC–Ru–CN–Ru, and would correspond for a linear geometry to a 10 Å distance. The V_{ab} coupling deduced from the intervalence band is ca 0.037 eV.

(NH₃)₅Ru(NCN⁻)

The bridging ligand dicyanamidobenzene and its dichloro- and tetrachloro-substituted variants have been studied extensively by Crutchley and co-workers [20]. It exhibits unusual properties from the point of view of antiferromagnetic coupling when ruthenium is in oxidation state III, and provokes also large wave splitting in cyclic voltammetry for metal–metal distances of 13.1 Å. For intervalence transitions, the situation is complicated by the overlap with intense LMCT bands of the ruthenium(III) chromophore. An intriguing effect is the great sensitivity of the intervalence transition to the solvent, the band appearing as a simple shoulder in D₂O, but as a well-resolved and isolated band in acetonitrile [20d]. This is attributed to the specific interaction between the solvent and ammine protons. In acetonitrile, the dicyanamido ligand gives a 980 cm⁻¹ (0.122 eV) coupling from Hush’s formula [63]. It is possible to prepare longer homologs of dicyanamidobenzene, such as the 4,4′-dicyanamidobiphenyl dianion, the metal–metal distance reaching 17.2 Å [64, 65]. The corresponding complex gives a 400 cm⁻¹ (0.050 eV) coupling.

(NH₃)₄(py)Ru(NCN⁻) and (NH₃)₃(bpy)Ru(NCN⁻)

Again, complexes with these end groups derived from the dicyanamido ligand are reported by Crutchley [66, 63]. Intervalence transitions have been observed and exploited to give V_{ab} values which are found, through Hush’s equation [63], in the 800–1100 cm⁻¹ range (0.1–0.13 eV). Another estimation of the metal–metal coupling was performed through the CNS model [66], giving much higher values.

However, this treatment [39] is an *indirect* estimation, because it is not based on the intervalence transition, but on the parameters of the ligand-to-metal charge transfer transition appearing in the ruthenium(III) chromophore. The values obtained by this procedure are thus difficult to compare to the other ones mentioned in this review.

(bpy)₂(Cl)Ru(py⁻) and (bpy)₂Ru(bpy⁻)

Complexes with (bpy)₂(Cl)Ru bridged by 4,4'-bipyridine, or bipyridylethylene were prepared by Meyer et al., but unfortunately they exhibit lower couplings when compared to the analogous ruthenium(pentaammine) compounds [1, 67a]. This is attributed to the competitive effect of π -acceptor ancillary ligands which drain the electron density away from the bridging ligand [67b].

Deprotonation of a binuclear complex with (bpy)₂ClRu moieties and 1,5-dipyridyl-1,3-pentadiene as bridging ligand yielded the cyanine-bridged complex, contrarily to the unsuccessful case of the bis(pentaammine)ruthenium complex (cf. (NH₃)₅Ru(py⁻) above) [14a]. However, cyclic voltammetry and spectroelectrochemical studies revealed that oxidation occurred at the cyanine bridging segment rather than on ruthenium atoms, thus precluding the preparation of a mixed-valence species.

A mixed-valence complex of Ru(bpy)₂ bridged by 1,10-bis[4'-methyl(2,2'-bipyridyl)]-3,8-dimethyl-1,3,5,7,9-decapentene, i.e., with five double bonds constituting the spacer between 2,2'-bipyridine ligands, has been described by Lehn and co-workers [32b]. Hush's analysis of the intervalence transition gave $V_{ab} = 0.018$ eV for a 24 Å metal-metal distance.

(terpy)Ru(terpy⁻)

These complexes, prepared by Collin and Sauvage, are made from a bridging ligand in which two terpyridine groups are connected either directly back-to-back, or via a polyphenylene spacer (C₆H₄)_n, $n = 1, 2$ (series **2**). Starting from the ruthenium(II) complexes, the oxidation by Ce(IV) in acetonitrile yielded the mixed-valence species, and Hush's analysis gave the corresponding V_{ab} couplings [16b]. The decay slope for the $\ln(V_{ab})$ vs. R plot was -0.084 Å^{-1} . The high values of the redox potentials (ca 1.3 V vs. SCE) was however a drawback of this series, since oxidized species were not stable for long periods and titrations had to be performed rapidly.

Cyclometallated species (see (terpy)Ru(dpb-) below) represent a significant improvement in this respect.

(bpy)(terpy)Ru(NCN-)

A complex with Ru(bpy)(terpy) moieties bridged by the dicyanamido ligand has been described by Crutchley [15a]. The mixed-valence ion presents an intervalence band at 1090 nm, and the authors assign the system to class III, resulting in a high V_{ab} coupling (half the optical energy, giving 0.57 eV). However, since the band is moderately intense ($\epsilon = 5600 \text{ mol}^{-1} \text{ L cm}^{-1}$), a class II nature could also have been considered, and in such a case, from the published values, Hush's equation would give a 0.058 eV value. (Treating such complexes either as class II or class III systems results in large changes in V_{ab} .)

(terpy)Ru(dpb-)

These complexes, prepared by Collin and Sauvage, are structurally similar to those of the bis(terpy) family ((terpy)Ru(terpy-) described above), but with the nitrogen atom of the central ring replaced by a carbon atom (cyclometallated species). The spacer between the dipyridylbenzene coordination sites can be made of 0 to 3 phenylene units, the metal-metal distance ranging from 11 to 24 Å (series 3). Starting from the ruthenium(II) state, the oxidation occurred more easily (ca. 0.5 V vs. SCE) than for the corresponding bis(terpyridine) complexes, and a much stronger coupling was observed for the mixed-valence species [17c,d]. However the rate of decay in the $\ln(V_{ab})$ vs. R plot was faster (-0.118 Å^{-1} instead of -0.084 Å^{-1}). This key observation is discussed in more detail in the conclusion. Note that the mechanism of electronic coupling, and in particular the effect of replacing a nitrogen atom by a carbon, can be addressed by molecular orbital calculations [17d]. It was found that the theoretical predictions were very sensitive to the energy of the Ru(4d) orbitals, which unfortunately are somewhat arbitrarily positioned in conventional Extended Hückel calculations. However, with the help of the ZINDO method, it was possible to justify the choice of the ruthenium orbital energies, and to reproduce the main features of the series.

This series also allowed an investigation of the influence of the position of the carbon atom substituting for nitrogen in the basic bis(terpyridine) framework. The highest efficiency for intervalence electron transfer was found when the carbon atom was located on the metal-metal C_2 axis of the molecule.

(terpy)Ru(bdmab⁻) (bdmap = bis(dimethylaminomethyl)benzene)

The bis(dimethylaminomethyl)benzene ligand (“pincer”) developed by Van Koten is an interesting cyclometallating ligand giving complexes very similar to the ones of dipyridylbenzene ((terpy)Ru(dpb⁻)). With two such complexing parts connected back-to-back (“bis-pincer”), it is possible to prepare strongly coupled bimetallic complexes with 10.8 Å metal–metal distance [68]. An intense intervalence band ($\epsilon = 33\,000 \text{ mol}^{-1} \text{ L cm}^{-1}$) was observed, and computing V_{ab} from the Hush formula gives 0.165 eV, i.e., more than for the analogous bis(dipyridylbenzene) complex. (Considering the system as class III would even give $V_{ab} = 0.33 \text{ eV}$).

(bpy)₂Ru(pp⁻)

These are also cyclometallated species, but based on complexation by the 2-phenylpyridine part. The spacer can be one or two triple bonds, or diethynylaryl groups (aryl = 9,10-anthrylene, 2,5-thienylene, or 1,4-phenylene), constituting series 4. As for cyclometallated complexes of the dipyridylbenzene family, the oxidation is easy (ca. 0.5 V vs. SCE), and the intervalence transitions are relatively intense, although partly overlapped by a nearby charge transfer transition of ruthenium(III) [18b,c]. For a given length, the couplings obtained are generally intermediate between those of the bis(terpy) and dipyridylbenzene families, and the decay slope is -0.104 Å^{-1} if the complex with a diethynylanthracene spacer is excluded. The latter exhibited a particularly strong coupling, which is discussed below (see Section 1.6.3)

**(bpy)₂Ru(N–N) (N–N = benzimidazolyl-pyridine site)**

In these complexes, the two Ru(bpy)₂ terminal moieties are bridged by a 2,2'-bis(benzimidazol-2-yl)-4,4'-bipyridine ligand, the metal–metal distance reaching 11 Å [69]. An intervalence band has been observed at 1200 nm, from which a 120 cm⁻¹ coupling (0.015 eV) is determined. Although this value is low in comparison with other complexes, the system is extremely appealing, since the intervalence band, and thus the coupling, can be switched OFF upon deprotonation.

(NC)₅Fe(py⁻)

Mixed-valence complexes based on this end group were first developed by Felix and Ludi [70], and their basic properties are reviewed elsewhere [1]. The longest system is based on the bis(pyridyl)ethylene ligand, and the metal–metal separation (14 Å) is

large enough to study ionic association effects in a situation where the redox centers interact independently with the environment [21]. It can be shown for instance that stepwise ion pairing occurs when highly charged counterions are added, with symmetry reduction, and subsequent restoration when the two ends of the mixed-valence ion are associated with counterions to the same extent.

(Cp)Fe(Cp-)

A series of α,ω -diferrocenylpolyenes with $n = 1-6$ conjugated double bonds have been prepared and studied upon electrochemical oxidation in dichloromethane by Launay, Spangler, and co-workers [71a] (series 5). Intervalence transitions were obtained and gave the electronic coupling terms as a function of the number of double bonds. Although the decrease with distance was essentially exponential, a small but significant deviation was observed for $n = 3$, suggesting that there could be two regimes for the decay law, one from one to three double bonds, and the other one beyond.

Ferrocene-containing molecules present some drawbacks, however, such as a weak solubility and a tendency to decompose upon oxidation. Substituted ferrocenes, in particular pentamethylferrocenes, are interesting alternatives. With a spacer made of three phenylene and four vinylene units, an intervalence band has been obtained, corresponding to a 0.01 eV coupling for a metal-metal distance of 26.5 Å [71b].

An interesting spacer is provided by the ruthenium bisacetylide group. When inserted between two ferrocene end groups, it gives a rigid linear system for which iron-iron intervalence bands have been observed [72]. The metal-metal distance is modest, however (ca. 10 Å); from the published spectra, one can compute V_{ab} values in the 0.06–0.08 eV range.

Another special spacer consists of porphyrin (either metallated or not) substituted in the 5,15 positions (see Figure 12b). Intervalence transitions have been observed when the ferrocene groups are electrochemically oxidized [36]. The metal-metal distance is >10 Å. No estimation of the V_{ab} coupling was reported, but the mixed-valence compounds would correspond to class III, or II/III.

(Cp*)(dppe)Fe(C≡C)-

Organometallic species presenting intervalence transitions through bridges essentially made of carbon atoms have been described by Lapinte and co-workers. The end group is (Cp*)(dppe)Fe(C≡C)-, where dppe = ethylenebis(diphenylphosphine),

and the spacer is either a phenylene unit or two triple bonds. The bridging ligand (see Figure 2 for the distinction with respect to spacer) is either 1,4-bis(ethynyl)-benzene (metal–metal distance 11.9 Å) [73] or octatetrayne (metal–metal distance 12.6 Å) [74], i.e., a chain of eight sp-hybridized carbon atoms (series **6**). The synthesis gives initially the 18e–18e species (formally Fe(II)–Fe(II)), which can be quantitatively oxidized to the 35e mixed-valence species, thanks to a large comproportionation constant (wave splittings 0.26 and 0.43 V respectively).

For the complex bridged by 1,4-bis(ethynyl)benzene, the experimental evidence (Mössbauer, ESR, IR) shows a borderline behavior between classes II and III. The electronic coupling is then either 0.064 eV (class II) or 0.31 eV (class III) [73]. For the complex bridged by octatetrayne, the class III behavior appears most likely (from the IR spectrum, and the sharp intense intervalence transition), giving $V_{ab} = 0.32$ eV [74]. This appears to be the largest coupling observed for such a distance (the less likely treatment as class II would give 0.09 eV) and shows the promise of all-carbon bridges if the synthesis can be extended. Still longer all-carbon bridges are described later (Section 1.5.5, under “Electrochemical wave splitting”), but they have not been studied for intervalence transitions.

(dppe)(Cp)Fe(N≡C)–

In these organometallic species, terminal Fe(Cp)(dppe) units are linked by a square-planar Pt complex, either *trans*–[(py)₂Pt(CN)₂], or [Pt(CN)₄]^{2–}, resulting in a trinuclear Fe–Pt–Fe assembly with a 10 Å Fe–Fe distance [75]. Chemical oxidation in dichloromethane afforded the mixed-valence complexes which exhibited intervalence transitions near 1400 nm. From the published values, one can compute $V_{ab} = 0.038$ and 0.034 eV respectively.

1.5.2 Electron Transfer through a Monolayer at an Electrode

This kind of measurement being in its infancy, there is only one example for which systematic measurements on long molecules have been made [45]. It involves a series of rigid molecules with thiol at one end, linked to a ferrocene group through a poly(tolane) bridge. They were embedded in an inert long-chain thiol monolayer deposited on gold, and probed by AC voltammetry. With two to five tolane units,

the electrode–ferrocene length varies from 25 to 42 Å (series 7). The study by Creager et al. [45] yielded the intramolecular electron transfer rate constant and the $\ln k$ vs. R plot exhibited a slope of -0.36 Å^{-1} . Since k is proportional to V_{ab}^2 (cf. Eq. 5), this corresponds to a -0.18 Å^{-1} decay slope for V_{ab} .

1.5.3 Excited-state Electron Transfer

Among the large number of systems investigated [3], we concentrate on compounds for which a systematic study as a function of bridge length is possible. Several of them are based on the (terpy)Ru(terpy⁻) end group, and phenylene units are frequently used as spacers.

Bisporphyrin compounds linked by one to three phenylene spacers have been used by McLendon et al. to probe electron transfer between excited zinc porphyrin and Fe(III)(bisimidazole) porphyrin as acceptor site [76]. Electron transfer rates were deduced from the decrease in the lifetime of the first excited singlet state of the zinc porphyrin. The variation with the edge-to-edge distance between porphyrins gave a decay slope of -0.4 Å^{-1} . This dependence was attributed by the authors to the poor conjugation between adjacent phenylene rings twisted by 55° from each other.

Triads containing two Ru(II)(terpy)₂ end groups connected by one or two ethynyl spacers to a central Co(terpy)₂ moiety have been described by Ziessel, Harriman, and co-workers [77]. Upon excitation of the ruthenium chromophore, excited-state electron transfer from the central cobalt site occurs, as shown by spectral identification of the transient species. The electron transfer thus occurs at a distance of 15 Å.

Dyads of general formula [(ttpy)Ru(tpy)–(ph)_n–Rh(tppy)]⁵⁺ where ttpy = tolylterpyridine, and ph = phenylene spacer, with $n = 0–2$, have been studied by Sauvage, Scandola, and co-workers. Ru(II) and Rh(III) are thus rigidly fixed at distances varying between 11 and 20 Å. Time-resolved emission spectroscopy was first performed at low temperatures [78a], with the hope of observing the quenching of ruthenium(II) luminescence by electron transfer from excited Ru(II) to Rh(III). At 150 K, electron transfer quenching was only observed for the shortest member of the series ($n = 0$), while for the others it was too slow to compete with the decay of the excited state. This can be qualitatively rationalized using theoretical formulas for the electron transfer rate constant with V_{ab} values taken from the related work on

ruthenium mixed-valence complexes (see Section 1.5.1, under (terpy)Ru(terpy⁻)). At room temperature, electron transfer is fast enough to be detectable for the $n = 1$ complex, provided that emission measurements are brought to the picosecond domain [78b]. Although the decrease in the electron transfer rate constant with distance is evident, in practice the experimental window for studying the complete series is too narrow.

A very fascinating effect and still an open question is the wire-like behavior of DNA, in relation to radiation-induced damage. In an elegant study, Barton and co-workers, using well-defined systems, showed that DNA could facilitate photo-induced electron transfer between intercalated ruthenium and rhodium complexes with in particular a low decay coefficient (0.2 \AA^{-1} in terms of rate constant) [79a,b]. This value would correspond to 0.1 \AA^{-1} for the decay of the V_{ab} parameter, i.e., a behavior only encountered so far with really conjugated bridges of the type displayed in Figure 14. This appeared to conflict with other studies, in particular Brun and Harriman's work using organic intercalant molecules [79c], and also with theoretical expectations [79d] based on the similar case of electron transfer through proteins. Although the controversy is probably not finished [79e], an element of the solution could come from a recent theoretical work by Jortner et al. [79f], according to which two mechanisms could operate according to the nature of the intercalated donor and acceptor: a tunneling mechanism, strongly distance-dependent, and a hopping mechanism, much less dependent on distance.

1.5.4 Dexter-type Energy Transfer

Starting from the (terpy)Ru(terpy⁻) end group, bimetallic Ru(II)–Os(II) dyads with zero to two phenylene units have been studied (cf. Section 1.5.3). Energy transfer from Ru to Os has been observed, and assigned to a Dexter-type process from order-of-magnitude arguments [80]. Unfortunately, only a lower limit for k ($>10^{10} \text{ s}^{-1}$ for all complexes at 293 and 77 K) could be obtained.

With the Ru(II)–Rh(III) complexes mentioned above (Section 1.5.3), energy transfer from excited Rh(III) to Ru(II) occurs [78a]. Unfortunately, here also, only a lower limit for k ($>4 \times 10^5 \text{ s}^{-1}$ at 77 K, or $>3 \times 10^7 \text{ s}^{-1}$ at 150 K for all complexes) could be given, without the possibility of discriminating between the different compounds.

In the case of (terpy)Ru(terpy⁻) and (terpy)Os(terpy⁻) end groups linked by one or two ethynyl units studied by Ziessel and co-workers, triplet energy transfer from Ru to Os was also observed, but in this case rate constants could be obtained [81]. From these, assuming an exponential decay of k_{TT} with distance, the decay slope would be -0.17 \AA^{-1} for the rate constant, corresponding to -0.085 \AA^{-1} for the matrix element V_{TT} (cf. Eq. (7)).

Cyclometallated compounds of the type described in Section 1.5.1 under “terpyRu(dp⁻)”, but used as Ru(II)–Os(II) dyads, present remarkably different properties with respect to their bisterpyridine counterparts. In this case, the rates are appreciably lower and could be measured at 298 and 77 K from the quenching of

Ru-based luminescence [83]. The variation with bridge length (spacer of zero to two phenylene units) gave -0.33 \AA^{-1} for the decay law of the coupling.

A very interesting series has been prepared and studied by Balzani, Belser, De Cola and co-workers [82], in which $\text{Ru}(\text{bpy})_3$ and $\text{Os}(\text{bpy})_3$ end groups are connected by three, five or seven phenylene units, the metal-metal distance ranging from 24 to 42 Å. Energy transfer is deduced from the observed quenching of the Ru(II) phosphorescence, with a parallel sensitization of the Os(II) phosphorescence. Energy transfer rate constants vary from $6.7 \times 10^8 \text{ s}^{-1}$ for $n = 3$ to $1.3 \times 10^6 \text{ s}^{-1}$ for $n = 7$ at 293 K in acetonitrile, and a decay rate of -0.32 \AA^{-1} was established for the rate constants, corresponding to -0.16 \AA^{-1} for the matrix elements.

1.5.5 Other Effects

Spectroscopic evidence for delocalization

Several bimetallic complexes of Ru(II) present a special behavior, suggesting that in the excited state, an electron is promoted to an extended π^* orbital spanning the complete bridging ligand, which consequently plays the role of a wire. This is described on ethynyl-bridged binuclear ruthenium(II) complexes for which the triplet lifetime is abnormally long [84]. Incidentally, it is this property which allowed Ziessel and co-workers to develop bimetallic complexes in which excited-state electron transfer or energy transfer could be measured [77, 81]. With the bimetallic ruthenium complex bridged by bis(bipyridyl)decapentene (Section 1.5.1, under “ $(\text{bpy})_2\text{ClRu}(\text{py}-)$ and $(\text{bpy})_2\text{Ru}(\text{bpy}-)$ ”) [32b], the triplet lifetime was also long, which was attributed to the promotion of an electron on an extended orbital, with possible mixed-valence delocalization between the two bipyridyl subunits at either end of the polyene.

In the bimetallic ruthenium(II)–osmium(II) complex bridged by tetrapyridophenazine (tpphz) reported by Chiorboli, Gourdon, and co-workers [85a], the two metal atoms are fixed at a distance of 12.7 Å by the “ladder-like” polyquinoxaline ligand [85b]. Complete quenching of the $\text{Ru} \rightarrow \text{tpphz}$ MLCT emission, with sensitization of the $\text{Os} \rightarrow \text{tpphz}$ MLCT emission, was observed. Since here also the LUMO appears delocalized on the bridging tpphz ligand, the process can be viewed alternatively as energy transfer as well as electron transfer [85a].

In other respects, a bis(ferrocenyl)polymethine cation, in which two ferrocene end groups are connected by a polymethine spacer with up to 13 CH units, has been described by Tolbert et al. [14b]. The “molecular-wire behavior” is claimed, from the optical properties, in particular the absorption energy varying as the reciprocal of the chain length. In addition, separate oxidation potentials were observed for up to 13 carbon atoms between the metal centers.

Electrochemical wave splitting

As stated above, electrochemical wave splitting in itself cannot be actually considered as a manifestation of wire-like properties. However, some spectacular or intriguing examples deserve to be quoted.

Bimetallic molybdenum nitrosyl complexes, (containing Mo(I), i.e. a 17e species) with conjugated bridging ligands of the bipyridine family, or the bisphenolate family, present widely separated reduction waves, as shown by McCleverty, Ward, and others [86]. The separation can be observed with spacers containing up to four double bonds, or four phenylene units.

Bridges essentially made of carbon are also efficient in promoting such large wave splittings. Thus Lapinte and co-workers' organometallic iron complexes bridged by 1,4-bis(ethynyl)benzene or octatetrayne [73, 74] gave $\Delta E_{1/2}$ values of 0.26 and 0.43 V for metal-metal distances of 11.9 and 12.6 Å respectively. Longer systems, described by Gladysz and co-workers [34], are made of two (Cp*)Re(NO)(PPh₃) groups connected by a poly-yne chain reaching eventually 20 carbon atoms. Wave splitting is observed up to 16 carbon atoms (ca. 23 Å metal-metal distance).

Finally, complexes with (acac)Ru(III)(acac-) end groups and diethynylanthracene, diethynylthiophene, or triethynyl spacers, described by Hoshino et al. [19], exhibit wave splittings for the Ru(IV/III) couple (but not for Ru(III/II)). Interestingly, the diethynylanthracene spacer proved particularly efficient (cf. Section 1.5.1, under "(bpy)₂Ru(pp-)" for its role in mixed-valence compounds).

Magnetic effects

Intramolecular magnetic couplings are generally measured on compounds presenting relatively short metal-metal distances. A review of antiferromagnetic couplings reported up to 1979 by Coffman and Buettner [87] led to an empirical relation (Eq. (14)) for the maximum J values:

$$|J|[\text{cm}^{-1}] = 1.35 \times 10^7 \exp(-1.80 R_{\text{MM}}) \quad (14)$$

where R_{MM} is in Å.

Thus, for a 10 Å separation, the limit would be only -0.2 cm^{-1} . This small value arises from the fact that most known compounds at this time involved σ orbitals to propagate the exchange interaction. In particular, with copper(II) complexes, the unpaired electrons reside in a $d_{x^2-y^2}$ orbital which mixes with the σ system, but not the π one.

However, in 1978, Hendrickson and co-workers reported a value of -9 cm^{-1} for a binuclear copper(II) complex bridged by benzidine ($R_{\text{MM}} = 12.2 \text{ Å}$). The interaction was supposed to be propagated mainly by σ orbitals, with a possible role of π orbitals [88a]. Measurements on this complex *in solution*, to avoid intermolecular couplings, later gave a maximum value of 3.5 cm^{-1} for the $|J|$ parameter [88b].

Another attempt was performed by Julve, Verdager, et al. on copper(II) complexes bridged by 4,4'-bipyridine ($R_{\text{MM}} = 11.1 \text{ Å}$). Only a very weak coupling was obtained (-0.9 cm^{-1}), with no possibility of proving its intramolecular character [89].

Binuclear complexes with 17e molybdenum fragments of the type Mo(NO)Tp*Cl or MoOTp*Cl lead to larger couplings, as shown by Ward, McCleverty and co-workers. With 4,4'-bipyridine or 4,4'-bipyridylethylene as bridges ($R_{\text{MM}} = 11.3$ and 13.8 Å respectively), the couplings (-33 and -18 cm^{-1}) could be measured by

magnetic susceptibility down to 3 K [90]. Using bisphenates as bridging ligands, a coupling of -13.2 cm^{-1} was obtained for a distance estimated at 13.9 \AA . For all these complexes, studies with positional isomers, or crowded systems twisting the 4,4'-bipyridine ligand, demonstrated clearly the intervention of the π system.

At the present time, the largest couplings are reported by Crutchley and co-workers [20c], using dicyanamidobenzene bridging ligands (or chloro-substituted variants) with rutheniumpentaammine fragments. Unprecedented couplings in the -120 to -200 cm^{-1} range for a metal-metal distance of 13.2 \AA were reported, one of the complexes even being diamagnetic ($|J| > 800 \text{ cm}^{-1}$). This was explained by the strong mixing between $\text{Ru}(4d)$ orbitals and the HOMO or second HOMO of the bridging ligand. However, the analysis failed to recognize that it is not the properties of a single orbital (even spanning the whole molecule) which determines a strong coupling, but the *difference* in mixing between in-phase and out-of-phase combinations of metal orbitals with ligand orbitals.

To summarize, it appears that few systems have been devised to exhibit long-distance magnetic couplings. Compounds derived from dicyanamido complexes appear promising candidates, and for longer systems, magnetic susceptibility studies could be complemented by EPR, which is more appropriate to measure small couplings.

1.6 Conclusions

1.6.1 The Decay Law

A number of effects or parameters vary with distance according to exponential, or almost exponential, laws. This is of course the case for the basic V_{ab} parameter, and this occurs also for several related experimental observables, such as electron and energy transfer rate constants, and also magnetic J couplings. This general behavior is ultimately linked to orbital overlap considerations, and is discussed in more detail below for the case of mixed-valence compounds.

In the case of nanojunctions, an exponential law is also predicted [91], and was very recently amenable to an experimental verification [5c]. This confirms the relationship between molecular model systems studied in solution, and actual devices involving an electrical connection to the outside world.

Magnetic couplings seem also to decrease exponentially with distance, but as stated above, there have been few systematic studies of the rate of decay through conjugated bridges, the compilation by Coffman and Buettner being empirical, and limited to σ -mediated interactions [87].

Let us consider in more detail the case of mixed-valence complexes, for which systematic studies on several series of compounds are available. Most results can be summarized in Table 2, and Figure 14, where the key parameter V_{ab} , on a log scale, is plotted against R_{MM} . As stated above, it usually displays an exponential decrease (except in the case of bis(ferrocenyl)polyenes, for which a small but significant de-

^aslope computed from the first four compounds of the series only, ^bsee refs. [20d, 63, 66] for additional values with related ligands and different solvents, ^ccomputed from reported $E_{1/2}$ values, ^{d,e} V_{ab} values when considered as a class II system (Hush equation), or class III ($V_{ab} = \bar{\nu}/2$), respectively.

Figure 14. V_{ab} values, from intervalence measurements, on a log scale, as a function of the through-space metal–metal distance: +, ruthenium bipyridylpolyene complexes (series 1); ●, ruthenium bis(terpyridyl) complexes (series 2); □, ruthenium bis(cyclometallated) complexes, dipyritylbenzene family (series 3); *, ruthenium bis(cyclometallated) complexes, phenylpyridine family (series 4); ▲, bis(ferrocenyl)polyenes (series 5). Additional measurements: a, bis(cyclometallated) complexes, phenylpyridine family with diethynylantracene as spacer; b, bis(ferrocene) with three phenylene and four vinylene units as spacer; c, bis[ruthenium(trisbipyridyl)] with five double bonds as spacer. Note that the $\text{Cp}^*(\text{dppe})\text{Fe}$ system bridged by octatetrayne (13 Å, 0.32 eV) is outside the graph.

parture has been observed, i.e., there are two slopes, one up to three double bonds, and another one thereafter [71a]).

A simple tight-binding model has been proposed by McConnell [92], which describes a donor–bridge–acceptor system (this can be adapted to mixed-valence systems composed of two terminal sites and N repeat units) with three parameters: α , the coupling between equivalent repeat units constituting the bridge; β , the coupling between the last unit of the bridge and one terminal site; and “a”, the energy difference between terminal and bridge sites (Figure 15).

This model allows the determination of the effective coupling V_{ab} , and its decay with distance. However, while the original McConnell treatment relied on perturbation theory, an exact analysis was performed by Joachim et al. [59, 93], and shortly afterward developed by Hush and co-workers [62, 94]. The complete analysis predicts a wide variety of behaviors according to the values of the parameters: slow or fast decay, exponential or nonexponential character, oscillations, and even

Figure 15. The simple tight-binding model, with α , β , and “a” parameters.

an increase in coupling with distance [62]. In a refinement of the original model, the effect of alternation, i.e., the existence of two different intra-bridge couplings β_1 and β_2 , was also considered [59, 62]. The frequent occurrence of exponential decay [95] is a general behavior when, as usual with most conjugated bridges used in mixed-valence chemistry, the metal energy levels fall in the “gap” of the bridge backbone, i.e., they are far from resonance.

Finally, when compared to intervalence electron transfer, Dexter-type energy transfer gives widely different decay laws (expressed in terms of $\ln V_{\text{TT}}$ vs. R), i.e., from -0.085 to -0.33 \AA^{-1} . No simple explanation appears at present, due to the higher complexity of the process. One can only remark that, since the matrix element V_{TT} appears as the *product* of matrix elements for electron transfer and hole transfer (Eq. (7)), one can expect the rate of decay with distance to be the *sum* of the rates of decay for these two processes [46a, 83]. This would explain why the decay is generally faster than for electron transfer, with the curious exception of Ziessel’s acetylene-bridged complexes (see Section 1.5.4).

1.6.2 Cyclometallated Compounds

The most striking point from Figure 14 is that many compounds with very diverse structures fall in the same area, giving similar V_{ab} values, and decay slopes in the range -0.07 to -0.10 \AA^{-1} . Cyclometallated compounds, on the other hand, exhibit a special behavior, characterized by a larger V_{ab} , but also a *larger decay slope*. This is particularly true for compounds where the coordinating site is of the bipyridyl-benzene family (Section 1.5.1, “(terpy)Ru(dpbb-)”), but the trend is also very clear with compounds of the phenylpyridine family (Section 1.5.1, “(bpy)₂Ru(pp-)”). To use the simple tight-binding model above as an explanatory tool, it is necessary to have at least a rough idea of the change in the formal α , β , “a” parameters from one compound to the other.

According to molecular orbital calculations, the main difference between bis(terpyridyl) complexes and cyclometallated ones lies in the tail of the wave functions with mainly metal character. In the case of cyclometallated compounds,

they have a greater extension on the carbon atom located *para* to the ruthenium–carbon bond, thus ensuring a better communication with the spacer [17d]. In the framework of the simple model above, this is equivalent to an increase in β , and the model indeed predicts an increase in V_{ab}^0 , and an increase in the γ decay coefficient.

Thus it does not seem possible, in general, to win on V_{ab}^0 and γ at the same time [59]. In other words, the “ V_{ab}^0 vs. γ ” competition appears inherent to the structure of any compound made of repeat units. The above tight-binding model is however limited, because assigning just one energy level to one repeat unit does not take into account the detailed structure of the latter. Actually, each of the repeat units may exhibit several energy levels with different energies and symmetries. More recent treatments take this explicitly into account [91], and could help in the selection of the most efficient structures.

1.6.3 Puzzling Compounds

Among the values reported in Figure 14, several compounds are really exceptional:

complexes linked by bridges made of pure carbon, which exhibit record values of the coupling, although for modest distances. In addition, they produce record values of the length/width ratio. Very long systems of this kind have not yet been studied as mixed-valence compounds.

compounds involving a diethynylanthracene spacer. With (acac)Ru(III)(acac–) end groups they give a high wave splitting (cf. Section 1.5.5, “Electrochemical wave splitting”), and with (bpy)₂Ru(pp–) end groups (Section 1.5.1, “(bpy)₂Ru(pp–)”) the V_{ab} coupling is *higher than without the anthracene part of the spacer*. This very strange effect has been also observed with dimers of porphyrins linked by a 9,10-diethynylanthracene spacer [96]. The electronic communication, measured by the red shift of luminescence, is higher than for a shorter dimer *without* the anthracene part.

These two intriguing classes of compounds have a common point: the possibility to write an alternate mesomeric structure, either quinoidal or cumulenic, for the fully oxidized form containing ruthenium(III) or iron(III) [23, 68, 73, 96]. The relationship with the high value of the coupling in the mixed-valence state is at present unknown, but deserves further investigation.

1.6.4 Mixed-valence Complexes and Metal/Molecule/Metal Nanojunctions

The comparison with theoretical estimations on metal/molecule/metal nanojunctions could be fruitful since, in both approaches, one tries to optimize the pre-exponential term and the decay slope. A recent systematic theoretical study by Joachim and Magoga has ranked a large number of bridge structures, made of several repeat units [91]. They were characterized by the value of the conductance, and its rate of decay with distance. The comparison with the compounds of the

present review cannot be pushed too far, however, because there are relatively few repeat units common to the two studies, and moreover, the existing mixed-valence compounds usually involve a small number of repeat units in the bridge (a maximum of three vs. more than ten in the theoretical work on nanojunctions). But several intriguing facts appear: a) again, bridges made of ethynylanthracene units appear very promising, giving here a small rate of decay of the conductance with distance; b) conjugated triple bonds (which have not been very much used in mixed-valence chemistry) appear better than double bonds, provided they are not introduced alone in the structure, but associated with an aromatic cycle. This is contrary to naïve intuition since, for an infinite system, triple bonds give a higher gap than double bonds, but the study demonstrates that the band gap is not the only factor determining the efficiency.

2 Approaches to an Optically Controlled Molecular Switch

Aaron S. Lukas and Michael R. Wasielewski

2.1 Introduction

At the dawn of the 21st century our fundamental understanding of complex processes such as photosynthesis and gene replication has reached the molecular level. The ability to observe ultrafast chemical and physical processes as well as these events occurring in single molecules [1] was unknown a mere 30 years ago. In the coming decade researchers hope to synthesize concepts gleaned from research in these fields and develop a computer whose operation is based on the interactions of single molecules with one another. This computer has the potential to be orders of magnitude smaller, faster, and more efficient than those based on semiconductor technology [2–4]. Massive size reductions using molecular switches will most likely be limited by quantum statistical considerations, if reasonable data error rates are to be maintained [5]. Nevertheless, molecular devices that use visible light for addressing and control purposes have a realizable data density of $\sim 2 \times 10^9$ bits cm^{-2} just through diffraction-limited spot size considerations alone. Recent results suggest that three-dimensional addressing [6], the use of excitonic waveguides [7, 8], and near-field optical techniques [9, 10] can greatly increase this resolution. Furthermore, since energy and electron transfer processes can occur on a sub-picosecond time scale, it is possible to produce devices that respond with equal rapidity. Employing high quantum efficiency, fast photo-driven processes will also decrease the heat load produced by the current computing devices. This results in a more energy efficient system, and may result in economically viable molecular electronic devices.

Nonetheless, a working device has yet to be realized. Successful examples of molecular systems capable of rectification [11, 12], wiring [13–44], memory storage [6, 45–49], and switching [50–57] have been demonstrated; however, integration of these various components has proved difficult.

The development of a paradigm to guide this undertaking is an active area of research [58, 59]. One promising approach is to base such a device on the interaction of light with these various components [60–64]. There are several advantages to performing switching operations via optical inputs and outputs. Electronic ab-

sorption is an extremely rapid process, and it should be possible to create switching devices that respond equally rapidly. The excited states of molecules can fluoresce, undergo electron and energy transfer, and lead to bond making and bond breaking. Each of these processes can be used for switching and storing data. Variable addressing of molecular states can be achieved by modulating the wavelength, intensity [65], polarization, and temporal and spatial properties of laser pulses. Information can be read from these systems via fluorescence [66], spectral bleaching [67–76], circular dichroism [77–79], the readout of electronic spin states, and other techniques.

Great strides have been made in recent years towards the development of electronic devices based on the interaction of single molecules with light. Switching systems based on photochromic behavior [30, 45–47, 66, 80–101], optical control of chirality [78, 79, 102], fluorescence [103–108], intersystem crossing [109–113], electro- and photochemically induced changes in liquid crystals [114–119], thin films [73, 120–129], and membranes [130, 131], and photoinduced electron and energy transfer [132–150] have been synthesized and studied. This review will briefly discuss recent developments in photochromic-type devices as well as giving a detailed look at the development and applications of molecular switches based on photoinduced energy and electron transfer processes.

Experimental work has focused mainly on approaches to molecular switches that make use of photochemical and electrochemical conformational changes within molecules. The general class of molecules to be discussed has several distinguishing properties. It is any molecule or array of molecules capable of absorbing a photon at a first wavelength, λ_1 , which induces a change in its electronic and/or nuclear structure. This structural change does two things: it attenuates the absorption of a second photon at λ_1 and introduces a new absorption at a second wavelength, λ_2 . The switch has been turned “on”. The switch can be turned “off” in one of several ways. We will examine systems whose lifetime is modulated thermally, magnetically, and also via absorption of a photon at this second wavelength, λ_2 , or in some other part of the spectrum. The lifetime of the “on” state determines the turnover time and also the potential applications of a switch. Molecules with very long state lifetimes are no longer switches, but are considered to be memory devices.

The operation of any optically controlled device is critically dependent upon the efficiency of light absorption by the input chromophore, and its ability to undergo electron transfer. Three characteristics make an excellent input chromophore: a large ground state extinction coefficient, long-lived excited state (in the region of several nanoseconds), and high fluorescent quantum yield. The most commonly used chromophores for light absorption are fused polycyclic aromatic hydrocarbons, metallated and free-base porphyrins, and derivatives of other light absorbers found in nature.

The electronic state of the switch is often read by using optical transient absorption and fluorescence emission spectroscopies. Fluorescence is a much more sensitive technique, and can be used even at the single molecule level. It also requires a much smaller density of photons to provide a stable signal; however, very few charge-separated ion pair states exhibit radiative charge recombination. In these cases transient absorption is often used because it allows direct nondestructive observation of a molecule’s electronic configuration. Problems with this technique

include photodegradation of more sensitive biological systems. Also, transient absorption is difficult to perform on monolayers or in the solid state, where absorption cross-sections are much lower than in solution. For this reason monolayers and thin-film assemblies are generally characterized by fluorescence emission or other more sensitive techniques.

2.2 Systems Consisting of Single Molecules

Perhaps the simplest optically controlled switches are single molecules embedded in a solid host matrix. These systems consist of an amorphous, polycrystalline, or crystalline film doped with dilute concentrations of impurity molecules. The most commonly used dopant molecules are fused polycyclic aromatic hydrocarbons and porphyrins. In addition to facilitate sample preparation, these planar molecules absorb in the visible to near-IR regions of the spectrum, possess large extinction coefficients in both the ground and excited states, and have high fluorescence quantum yields.

2.2.1 Two-level Systems

Theoretically the simplest molecular switch is a two-level system (TLS) consisting of a double well potential in which two near-degenerate states are separated by a potential barrier [151]. Single molecules embedded as dilute impurities in solid media demonstrate TLS properties. The study of these systems for optically controlled molecular switching is an active area of research [152–158]. The most commonly studied impurity molecules are pentacene (**1**), perylene (**2**), and terrylene (**3**). The coupling of single or multiple nearby TLSs results in spectral diffusion in the emission spectra from these single molecules. The TLS behavior may arise from structural relaxation within the single molecule, or more likely from small rearrangements of the surrounding medium. Structural fluctuations in the medium are likely to be coupled to phonon excitations in the impurity molecule. Although initial work on TLSs suggested this effect should be observed only in amorphous solids, it has also been observed in polycrystalline matrices [154] and crystalline [158] solids.

The switching lifetime of the resonance frequency has been observed to exhibit an exponential dependence on the intensity of irradiation [154]. The intensities of the emission lines from each state are proportional to the probability of the TLS population in that site. This ratio is given by

$$\exp(-\Delta E/kT) \quad (1)$$

where ΔE is the energy separation between sites. When many TLSs are coupled to a single molecule, multiple resonance frequencies are observed [154].

Investigation of the microscopic origin of these TLSs has demonstrated the ability to modulate resonance shifts in single molecules by interrogation of neighboring solvent molecules coupled to the system [155]. Doping of poly(methyl methacrylate) with free-base phthalocyanine and small amounts of water shows that reorientation of nearby water molecules is the source of spectral diffusion observed in the phthalocyanine.

These systems demonstrate the possibility that an optical switch can be based on photochemical manipulation of a single molecule's electronic state and local environment. However, these systems also possess several limitations. First, these switching phenomena are observed only at liquid helium temperatures. Second, these systems suffer from photobleaching at relatively low photon densities. Third, single molecules do not allow for broad spectral coverage. Whereas perylene, terrylene, and porphyrins all have large extinction coefficients, their absorption bands are only 20–50 nm wide. In some cases it may be desirable to incorporate light-absorbing antenna complexes to enhance this spectral coverage. By selecting molecules on the basis of their spectral and electrochemical properties it should be possible to cover any region of the visible spectrum. This should also improve the lifetime of these systems because a single molecule need not absorb photons during each clock cycle, which can lead to photodegradation. Fourth, switching events based on a TLS are on the order of seconds to minutes, and are likely to have greater application to optical data storage. Lastly, one cannot take full advantage of the gains in data storage density provided by such systems unless improvements are made in our ability to address single molecules. These experiments are performed in dilute solid solutions wherein single impurity molecules can be easily addressed without interference from neighboring molecules. This technology has yet to be applied to arrays of molecules in close contact with one another. This leap must be made before consideration can be given to devising high-density data storage systems based on TLS switching.

2.3 Photochromic Systems

Photochromic molecules undergo reversible photoinduced color changes based on structural rearrangement. Generally, there is a stable configuration of the molecule which, when irradiated (often with ultraviolet light), undergoes a large change in its absorption spectrum. Conversion back to the original form of the species is com-

monly achieved via irradiation at a second wavelength or by the application of heat. Photochromic molecules undergo efficient internal conversion, taking excited-state electronic energy into vibrational and torsional modes of the molecule. Thus, these molecules are characteristically nonfluorescent.

Photochromic processes are often observed both in solution and in the solid state, thus making for facile incorporation of photochromics in films, in membranes, and as dopants in host matrices—prerequisites for the construction of molecular optoelectronic devices. Section 2.3.1 focuses on the materials and supramolecular systems prepared from photochromic systems. For more comprehensive descriptions of the basic photochemical processes the reader is referred to any of the numerous reviews on the subject [47, 51, 89, 159–162].

2.3.1 Photoisomerizations

The most basic photochromic systems are those that undergo a light-induced structural rearrangement. Isomerizations often involve large nuclear rearrangements which, for example, can change the symmetry or convert from a linear to bent structure. This property is especially useful for doping of liquid crystals and thin films, in which the microscopic structure of individual dopant molecules can be used to modulate the macroscopic properties of a host system.

One of the most frequently exploited photochromic processes is the *cis-trans* isomerization of azobenzene. Irradiation of the more stable *trans* configuration with 360 nm ultraviolet light induces conversion to the *cis* isomer, which is stable for long periods in the absence of heat or light. Exposure to moderate heat or irradiation in the visible spectrum induces the transformation back to the *trans* species.

Azobenzenes have been incorporated into monolayers [124, 163], membranes [130, 164], Langmuir–Blodgett films [45, 165, 166], molecular sieves [167], oligomers [168], dendrimers [96, 169], polymers [170], and liquid crystals [116–119, 171–179]. When azobenzenes in an ordered environment are irradiated with polarized light a series of *trans-cis-trans* isomerization cycles is induced until a stable conformation is found. This alignment occurs with the optical transition moment of the azobenzenes oriented in the plane perpendicular to the polarization of the laser beam [180, 181]. The anisotropic alignment of the azobenzenes gives rise to local modulation of the refractive index of the material, forming the basis of optical data storage. In the absence of light or heat the azobenzene alignment is highly robust.

Berg et al. synthesized peptide oligomers that incorporated 4-cyanoazobenzene for erasable holographic data storage [168]. The oligomer is a diamino acid- N^{α} -substituted peptide (DNO) repeat unit, compound **4**, with an azobenzene side chain

(5). The DNO backbone imposes a helical stacking on the azobenzenes similar to that observed in DNA, with a twist angle of 36° between adjacent azobenzenes, as shown in Figure 1. Most importantly, the helical stacking imposed by the oligo-peptide limits considerably the number of potential stable stationary orientations that the azobenzenes may assume upon irradiation.

The DNO oligomers were cast as isotropic films $5\text{ }\mu\text{m}$ thick. Optical writing was achieved by overlapping two beams of circularly polarized 488 nm light from a continuous-wave argon ion laser at 2 W cm^{-2} . The writing time was observed to depend on the oligomer length, with the most efficient gratings forming in decamers ($n = 10$), implying a cooperative dynamic effect between adjacent azobenzene units. Optical reading was performed with the circularly polarized 633 nm output from a He:Ne laser at 4.2 mW . The gratings could be erased by irradiation with a single beam of circularly polarized 488 nm light. No fatigue in the system was observed for several read–write–erase cycles. The authors also discuss the effects of oligomeric stereochemistry, size, and side chain flexibility.

A second type of isomerizable system is a chiral molecule that can be photo-switched between two enantiomers. Changing the handedness of the light used for writing controls the relative concentrations of each enantiomer, and can provide the basis for a molecular switch. Each enantiomer has the same absorption spectrum

4 - UNIT HAIRPIN

Figure 1. The oligomer (4) forms a single-stranded helix in which adjacent azobenzene side groups are off-axis from one another by 36° . This stacking arrangement is nearly identical to that observed in DNA base pairs.

but the left- and right-handed isomers can be differentiated on the basis of their ability to rotate incident polarized light used for reading the state of the system [77, 78, 102, 127, 182].

An example of such a system is 12-(9'*H*-thioxanthene-9'-ylidene-12*H*-benzo[*a*]-xanthene, which can exist in two distinct states, compounds **6a** and **6b**. The free energy barrier for racemization is 25.9 kcal mol⁻¹. Irradiation of the **6a** isomer with circularly polarized light (CPL) at 300 nm resulted in photoisomerization to the **6b** isomer. The same wavelength of light was used for reading the state of the system, although with linear polarization. Circular dichroism (CD) measurements detect an ensemble average of a local domain determined by the spot size of the laser beam, and thus the racemic conversion need not be quantitative. The anisotropy factor [183] of the system determines the racemic excess that can be formed, and in hexane solutions of **6a** and **6b** an enantiomeric excess of only $\pm 0.07\%$ was achieved. However, this was easily detectable in the CD spectrum. The system is “erased” using linearly polarized 300 nm light. This effect was also demonstrated in the nematic phase of liquid crystals. Thus, such a system can be used as an optical switching device with the advantage of employing a single wavelength of light for writing, reading, and erasing. The same research group also synthesized a system in which the absorption spectrum was shifted to the visible part of the spectrum [77]. Operation at these more convenient wavelengths was achieved by the addition of electron-donating [$-\text{N}(\text{CH}_3)_2$] and -withdrawing groups ($-\text{NO}_2$) on the xanthene chromophore which produced an absorption at 435 nm. Furthermore, substitution of a sulfur atom at the 1-position of the xanthene resulted in a more robust switch.

Photoisomerizations can often occur by several different mechanisms. Systems that isomerize via a controlled mechanism are potential candidates for molecular machines [184]. Energy in the form of light is absorbed and converted to controlled mechanical force on the molecular scale. Examples of a mono-directional rotor [185, 186], a switchable rotor [187], and a molecular shuttle [188] have been demonstrated. These systems are light-controlled, but there are also examples of systems which control molecular motion based on electro- and/or chemical modulation, such as the threading/unthreading of (pseudo)rotaxanes [189–196].

Biological molecules are often switched on and off by controlling the ligation environment or oxidation state of a metal center. The selective binding of ions [104, 197] and modulation of the binding environment of metal centers [79, 92, 198–204] have also been demonstrated as mechanisms for switching. The second of these examples is based on chemical modulation of the valence state of a metal or its

ligands, which induces nuclear rearrangement. This same principle can also be applied to organic chromophores.

A problem in constructing memory devices from photochromic systems is the inability to read the state of the switch nondestructively. Irradiation with visible light oftentimes leads to photodegradation, and erases the data after several read cycles. Thus, it is desirable to have some other means of reading the state of a switch: for example, the measurement of refractive index, IR absorption, or optical rotation. Another approach is to couple two reversible processes, such that once written to, the switch can be locked into a particular configuration. This can be effected electrochemically, via absorption of a second photon, or through binding of a free metal ion or proton. In essence, one has created a three-level switching system.

Most switches based on isomerizations are bistable; there are few examples of tristability [97, 98] or greater. Higher orders of stability in a single molecule preclude the need for high connectivity between adjacent switches. Thus, one switching device could accomplish the same logic operation as two switches linked together. One such example of a tristable organic molecular switch is a system that incorporates two dimethyldihydropyrene (DHP) units via a conjugated naphthalene bridge [97]. The switch is based on the photoinduced valence isomerization between the fully conjugated compound, **7a**, which contains two DHP groups and the nonconjugated bis(cyclophane)diene (CDP), compound **7c**. Irradiation with 427 nm light induced the **7a** \rightarrow **7b** \rightarrow **7c** switching process, resulting in the formation of a band in the ultraviolet region ($\lambda_{\text{max}} = 268$ nm) of the spectrum. The nonconjugated system was returned to its original state via irradiation at 313 nm, and furthermore displayed no degradation after 80 switching cycles. The advantage of this three-level system is that it is all-optically controlled; however, it is also difficult to stop at the intermediate state (**7b**). The creation of three-level systems in which all the forms are stable and distinguishable generally leads to coupling some other switching mechanism to a photochromic property.

A three-level switching device has been demonstrated in which photochromic properties are used to control electrical properties, and vice versa. Such a system has been realized in the form of thiophene bisphenol [90, 91]. Conversion of the open (**8a**) to the closed (**8b**) form of the thiophene was achieved by absorption of 312 nm light, and reversed by absorption of 600 nm light. The bisphenol oxidation occurs at +0.735 V (vs. SCE), forming the closed-ring bisquinone, compound **8c**. This species has large absorptions at 400 and 534 nm. The optical properties of the quinone–phenol couple have previously been used in a bianthrone-based system [87]. The bisquinone (**8c**) cannot be converted to the open thiophene, and locks the system in the closed form. The thiophene has also been incorporated as a component in two-level molecular switches [99, 128] and switchable molecular wires [30].

2.3.2 Open–Closed Ring Systems

Perhaps the most promising materials for all-optical write–read–erase switches are systems in which ultraviolet irradiation induces ring opening. One of the most studied systems are spiropyrans in which writing and nondestructive reading are based on successive two-photon and one-photon processes [46, 205–209].

Rentzepis and co-workers have employed spiropyran in methanol and a variety of polymer matrices [6], creating a three-dimensional arrangement of switching sites. Sites are selected within the polymer matrix via temporal and spatial overlap of two orthogonal laser beams tuned to the same or different wavelengths. The closed form of the spiropyran absorbs in the near-UV and was excited via two-photon absorption, from either the fundamental and second harmonic (355 nm), or two photons of the second harmonic (266 nm) output from a 1064 nm Nd:YAG laser. Rapid conversion to the open form placed the system in the “on” state and induced an absorption at 600 nm. This open system is also fluorescent, and excitation with either two photons of the fundamental or a single photon of the second harmonic (both 532 nm) resulted in a red-shifted emission. An energy level diagram of this system is shown in Figure 2. Writing to, addressing, and reading from the

Figure 2. Two-photon excitation of the closed spiropyran to the S_1 or S_2 state results in ring opening, and fluorescence from the S_1 state of the open-ring merocyanine species. The latter is stable and can be accessed for numerous “read” cycles via two-photon excitation with 1064 nm light. Switching back to the closed-ring spiropyran is achieved with mild heat.

sites all occur in different regions of the spectrum so that there is no cross-talk. This system is attractive because of the potentially high density of switches, parallel addressing capabilities, high sensitivity, and low cross-talk. Applying heat switched the system back to the closed-ring form. Further work has implemented spiropyrans as side groups on polymers [210], as dopants in films [211], and as single crystals [100]. This two-photon technique has also been implemented for the dimerization of anthracene [212] and the salicylideneaniline systems [213], in which the mechanism is proton transfer instead of ring opening.

The dihydroazulene–vinylheptafulvene couple (**9**) [85, 98], dihydroindolizine (**10**) [95], and fulgides are further examples of photochromic open–closed ring systems

that are potential three-level systems. Fulgides are derivatives of dimethylene-succinic anhydride, and their deactivated colorless form consists of *cis* and *trans* isomers, of which only the latter is convertible into the activated colored form [88, 214–217]. Similarly to spiropyran systems, fulgides consist of an open and closed ring system, and retain their photochromic properties when doped in films [94, 216, 218, 219] and liquid crystals [220]. The three forms of the 111D fulgide (Lancaster) can be interconverted based on their absorption of UV and visible light. Ultraviolet light induces a buildup of the closed form (**11**), which has a large absorption in the

visible region of the spectrum ($\lambda_{\text{max}} = 562 \text{ nm}$). The formation of **11** depends on the relative rates of the UV-initiated processes. The incorporation of fulgides into films presents the possibility of a molecular switch whose visible absorption or transmission can be modulated by UV light. Poly(methyl methacrylate) films of $1.2 \mu\text{m}$ thickness were doped with **11** and 611TD fulgide (Lancaster) [216]. Transmittance of visible light measured at 532 nm was modulated by irradiation of a pulsed UV emission, which resulted in 50 % attenuation of the visible transmittance.

2.3.3 Photorearrangements

Aromatic systems are apt to undergo rearrangements when irradiated with ultraviolet light. When the photoproducts are stable compounds with distinct absorption spectra, these reactions lend themselves to the construction of solid-state optical switches. One such system is 1-nitronaphthaldehyde [49]. A second system is the 2,4,4,6-tetraphenyl-4*H*-pyran and pyridine systems. They undergo a photoinduced rearrangement, converting compound **12a** to **12b** [83, 84]. The nonconjugated zwitterionic species (**12b**) has an absorption in the visible region which can be tuned by applying the appropriate electron-donating or -withdrawing substituents to the various phenyl rings [86].

There is no limit to the number of photochromic systems possible. The systems discussed are excellent candidates for integration into solid-state devices because nearly all retain their photochromic properties in the absence of solvent. The organization of these systems in tandem with other molecular systems is being pursued. For the switching applications many of these systems have much too slow a turn-over rate to be explored as working devices. That is unless the connectivity in these systems can be increased. In the meantime, photochromic systems will probably be explored as possible optical memory devices. The most promising switches are those based on the much faster processes of electron and energy transfer. We will now examine research in these areas.

2.4 Electron Transfer Based Systems

Theoretical work strongly supports the idea that an electron transfer reaction can form the basis for a molecular switch [12, 48, 221–223]. Yet the field has been slow to develop because the optimal use of electron transfer processes requires careful

control of molecular structure, electronic coupling, and thermodynamics in a complex array of donors and acceptors.

2.4.1 Intermolecular Electron Transfer

Photoinduced spectral hole burning [67–76] uses small fluctuations in the local environment to store bundles of information in a single molecule. In these systems the presence (or absence) of a spectral hole at a particular frequency is utilized to encode numerous bits of digital information within a single focused laser spot. In some systems the absorption of two photons encodes the data, while the readout is performed with a one-photon process [71]. These systems have the advantage of greatly increased readout speeds allowing for fast switching in small laser spots.

Carter and co-workers demonstrated spectral hole burning via an intermolecular electron transfer mechanism. In this experiment poly(methyl methacrylate) (**13**) films were doped with zinc tetrabenzoporphyrin (**14**) electron donors and chloro-

form (CHCl₃) electron acceptors. The formation of gated holes occurred when both the singlet–singlet and triplet–triplet absorptions were excited, as seen in the Jablonski diagram in Figure 3. Excitation of the ground state with 627 nm light (λ_1) results in triplet population with a quantum yield of 0.8. The lifetime of the triplet state is $\tau = 39$ ms. If a second photon arrives before this state decays then triplet–triplet transitions can occur. This excited state readily donates electrons to nearby acceptors, in this case chloroform molecules. The color of the second photon need not be specific, although the highest yield for electron transfer occurred with $\lambda_2 = 488$ nm. Electron transfer from two-photon absorption results in hole formation in the singlet manifold, and the observed photobleaching. The energy of the reduced CHCl₃ was not determined, but this system is likely to work with other electron acceptor groups. It is unclear if the free electrons can migrate between chloroform molecules, adding to the stability of the system; this is likely, however, considering the high concentrations of CHCl₃ used. Optimal electron transfer was

Figure 3. Energy level diagram for the zinc tetrabenzoporphyrin donor–chloroform acceptor system.

observed when chloroform was used in a molar excess of $10^5:1$. Furthermore, a weak electron acceptor such as chloroform makes the charge recombination a highly Marcus inverted process.

In their current form these systems have far more application to the construction of high-density optical memory devices. Several fundamental issues remain to be resolved before single molecules are widely used. At present these switching effects are observed only at liquid nitrogen temperatures or below. It should be possible to observe the same effects at ambient conditions. Also, cross-talk between molecules is likely to occur as the concentration of the dopant molecules increases and nearest neighbor interactions become important. But this may not be a problem, as the density of states should also increase in this situation, making possible even greater gains in the data storage capacity. It is clear that many of these questions will not be answered until the experiments are performed. Work on the single molecule level can also lend insight to covalently bound systems consisting of multiple subunits. We now examine such systems.

2.4.2 Intramolecular Electron Transfer

Covalently linked arrays of electron donors and acceptors can be used to perform switching operations. In addition, systems can be designed to store and transport digital information. One can tune both the optical and electrochemical properties of a multicomponent system by selecting the appropriate electron donors and ac-

ceptors. These systems are inherently more complex, yet allow for a wider range of applications than devices based on single molecules. Generally these systems consist of an input chromophore, a bridging group, and an output chromophore. Absorption of a photon results in one of two processes: stepwise photoinduced electron transfer resulting in a charge-separated state, or energy transfer followed by fluorescence.

An early hypothesis for a molecular switch based on stepwise photoinduced electron transfer appeared in 1988 [48]. The design describes a polymer consisting of a $[D-A_1-A_2]_n$ monomer unit wherein D is an electron donor moiety and A_1 and A_2 are primary and secondary electron acceptors, respectively. The system is designed to form a rigid photoactive chemical bridge capable of storing and transferring digital information between two electrodes. This is done via the synchronization of two processes: oxidation/reduction of the termini at an electrode and photoexcitation of the electron donor within the polymer.

The clock cycle for the switching process begins with photoexcitation of every electron donor in the polymer, forming the $[^1D-A_1-A_2]_n$ state. There are three potential deactivation pathways from this state to consider: fluorescence back to the ground state (dot), forward electron transfer to A_1 (solid), or backward electron transfer to A_2 in the adjacent monomer unit (dash-dot). A HOMO/LUMO scheme for these processes in the first three units of such a polymer is shown in Figure 4(a). The donor-terminated end of the polymer can decay only via the first two paths. It should be relatively simple to enhance the coupling between 1D and A_1 so that forward electron transfer is the preferential process. Spontaneous thermal electron transfer resulting in the state $[D^+-A_1-A_2^-]_n$, Figure 4(b), follows this initial charge separation step. This places free electrons and holes adjacent to one another on neighboring monomers. The basis for switching in this system is that electron tunneling between monomer units in this state (solid), which results in charge recombination, is kinetically preferred over charge recombination to the ground state within a single $[D-A_1-A_2]$ monomer (dash-dot). If one can control the electronic coupling to favor charge recombination across the unit, this leaves a single hole on the donor adjacent the cathode. The next phase in the clock cycle is the data writing process, which is done electrochemically. If cathodic current flows and returns the donor to its ground-state electronic configuration, then photoinduced electron transfer can occur from this donor site during the next clock cycle. However, if no reduction occurs, the hole will propagate along the polymer during the next clock cycle, leaving positive charge on the first two electron donors in the system. The holes are read out at the anode as 0s. The system must register n cycles before data entered at the cathode are read at the anode.

The authors discuss several parameters related to optimizing the efficiency of such a device. First, the chromophore that is photoexcited must possess a distinct absorption band having a large extinction coefficient. Other chromophores in the polymer should not absorb in this spectral region. The second concern is the ability for charge recombination to occur between monomer units. This process must be favored over charge recombination within a single monomer, or a switching error occurs. The free energy for each process is identical, and thus preference for one path over the other is based exclusively on the electronic coupling between the var-

Figure 4. HOMO/LUMO scheme for operation of a proposed molecular shift register [48]. a) The clock cycle is initiated by photoexcitation of the donor moiety, resulting in the electronic configuration shown. Decay pathways from this excited state are forward electron transfer within the same monomer unit (solid), back electron transfer to the adjacent monomer unit (dash-dot), and fluorescence (dot). b) Electronic configuration resulting from successive forward electron transfer steps. The charge-separated state $[D^+-A_1-A_2^-]_n$ can recombine charge within a single monomer unit (dot-dash) or with the adjacent monomer unit (solid).

ious sites. There are many examples of molecules with long-lived charge-separated states that would be appropriate for such a system. Even if tunneling through the barrier separating monomer units were slow, on the order of hundreds of nanoseconds, this could be much faster than charge recombination within the $[D-A_1-A_2]$ monomer. Bottlenecks can be avoided by encoding data to the polymer only on alternate clock cycles. This also improves the yield for charge shift between monomers. Thus, if tunneling had a quantum efficiency of 0.95, after two clock cycles this improves to 0.99 for transfer from a single monomer to the next. However, even a device with 99 % efficiency is not sufficient for a polymer with more than several repeat units. For a polymer of 100 repeat units the yield of transmission for a single bit through the polymer drops to 36 %. Many systems have been designed which undergo highly efficient long-lived charge separation appropriate for such a device [132, 224, 225], but as of yet no working system has been constructed.

In the proposed device the transport of holes is the basis for data transmission; however, polymeric and oligomeric systems capable of soliton propagation have also been synthesized and studied [15, 17, 32, 33, 35, 36, 38, 40, 43, 226]. Further examination shows that one could operate this system to transport negative charge along the polymer. In this scheme the clock cycle begins with the electrochemical encoding of data into the polymer. Reduction (or lack of reduction) of the ground electronic state of the donor adjacent to the electrode places a free electron into its LUMO. This reduced species undergoes spontaneous stepwise thermal electron transfer until the negative charge is localized on the last acceptor group in the first monomer, Figure 5(a). Radical anions of many organic chromophores have distinct spectral signatures with large extinction coefficients. Selective photoexcitation of the $[D-A_1-A_2^-]$ state gives an excited doublet state, with the electronic configuration shown in Figure 5(b). Optical switching is achieved by preferential charge shift from this excited state to the LUMO of the donor in the next monomer unit. Competitive charge shift to the adjacent acceptor will result in switching errors.

While such a device has not yet been constructed, Debreczeny and co-workers synthesized and studied a linear $D-A_1-A_2$ triad suitable for implementation in one [227]. In this system, compound **15**, a 4-aminonaphthalene monoimide (ANI) electron donor, is excited selectively with 400 nm laser pulses. Electron transfer from the excited state of ANI to A_1 , naphthalene-1,8:4,5-diimide (NI), occurs across a 2,5-dimethylphenyl bridge with $\tau = 420$ ps and a quantum yield of 0.95. The dynamics of charge separation and recombination in these systems has been well characterized [228]. Spontaneous charge shift to A_2 , pyromellitimide (PI), is thermodynamically uphill and does not occur. The mechanism for switching makes use of the large absorption cross-section of the NI^- anion radical at 480 nm ($\epsilon = 28\,300$). A second laser pulse at 480 nm can selectively excite this chromophore and provide the necessary energy to move the electron from NI^- to PI. These systems do not rely on electrochemical oxidation–reduction reactions at an electrode. Thus, switching occurs on a sub-picosecond time scale.

Excitation of the NI^- anion radical within ANI^+-NI^-PI with a 480 nm laser pulse rapidly forms the $ANI^+-^*NI^-PI$ excited doublet state. Its electronic configuration is analogous to that in Figure 4(b). There are two pathways for decay from this excited state: charge recombination back to yield the 1ANI excited state or charge shift to PI. The driving force for each of these paths is nearly identical, and

Figure 5. HOMO/LUMO scheme for a modified molecular shift register in which bits are encoded and propagate as free electrons instead of the hole transfer based system described in Figure 4. a) Data are encoded via electrochemical reduction of the donor moiety adjacent the cathode, resulting in the electronic configuration shown. Subsequent stepwise thermal electron transfer localizes the free electron on A₂. b) Excited doublet state resulting from photoexcitation of this species; it can decay via forward electron transfer (solid), back electron transfer (dash-dot), or internal relaxation processes (dot). Tuning of the energetics and electronic coupling to favor the forward electron transfer pathway propagates the charge to the next monomer unit.

thus the yield for each process is determined by electronic coupling. The electronic coupling between NI and PI is much greater than that between NI and ANI because no phenyl bridge separates them. As expected, this is the preferential path for deactivation, and can be observed directly by monitoring the formation of PI^- at 720 nm. Charge shift to PI occurs with $\tau = 300$ fs and a quantum yield of 0.88. The overall yield for the switching process is 0.84.

The electronic coupling can be changed by the insertion of a phenyl bridge between the NI and PI, compound **16**. Identical excitation of the NI^- with 480 nm laser pulses results in a much slower charge shift to PI, $\tau = 4$ ps, and a quantum yield of only 33 % [229]. It is clear that, as hypothesized, the ability to control electronic coupling between various sites is the determining factor in realizing the construction of a working device. However, enhancing the electronic coupling to favor the charge shift reaction from NI^- to PI also increases the rate for back electron transfer from PI^- to NI. The PI^- state undergoes back electron transfer to NI with $\tau = 600$ fs in **15** and $\tau = 312$ ps in **16**. It is likely that the addition of a third electron acceptor attached to PI could provide a lower-energy electronic state into which the system could relax, thereby reducing back electron transfer to NI. This would be more analogous to the polymeric systems described earlier.

Recent work has investigated the potential to control the partitioning of charge in branched arrays [230]. This has many potential applications to the development of photoactive networks and dendritic systems capable of electron transfer. Compounds **17** and **18** employ 1,3,5-triaminobenzene as the central branch point. In each molecule ANI is attached to the 1 position and serves as the electron donor. The electron acceptors again are NI and PI, and are attached to the 3 and 5 positions, respectively in compound **17**. Excitation of ANI with 400 nm laser pulses results in electron transfer exclusively to the NI branch. This is due to the 0.3 V

(17)

(18)

difference in reduction potentials between NI and PI. Excitation of NI^- within $\text{NI}^- - \text{ANI}^+ - \text{PI}$ with 480 nm laser pulses 2 ns after formation of this initial ion pair results in formation of an excited doublet state. This excited state can decay via charge recombination back to ANI or charge-shift to PI. The 720 nm absorption band of PI^- appears with $\tau = 600$ fs, and a quantum yield of 0.44. Competitive charge recombination to the $^1\text{ANI}^*$ excited state also occurs quite rapidly, $\tau = 500$ fs, and is the reason for the observed yield. The $\text{NI}^- - \text{ANI}^+ - \text{PI}^-$ state is 0.3 eV above that of the $\text{NI}^- - \text{ANI}^+ - \text{PI}$ state, and 2.7 eV above the ground state. Charge recombination to the ground state is a Marcus inverted process, and thus charge shift back to the initial charge-separated state, $\tau = 400$ ps, is the exclusive decay path. The lifetime of the electron on the second branch of the system was significantly enhanced by the addition of a lower-energy acceptor on the end of PI, in this case a second NI moiety. In compound **18** the rate of switching from branch 2 back to

branch 1 is $\tau = 2$ ns; however, the yield for the initial switching between branches decreases to 0.36.

The spin properties of charge-separated ion pairs can also be exploited for the purposes of all optical switching. Radical pair intersystem crossing (RP-ISC) of the form $^1[D^+-A^-] \rightleftharpoons ^3[D^+-A^-]$ to yield the spin-correlated triplet state is observed in the photosynthetic reaction center, but is seen rarely in synthetic systems. The reason for this observation is that the spin–spin interactions are generally strong, even in systems which undergo charge separation over large distances. However, the time for charge recombination within the triplet manifold is usually very different than that of the singlet state. An all-optical switch based on this property can be devised by controlling the rate, and thus the yield, of the intersystem crossing.

Wasielewski and co-workers [110] developed the first multistep donor(1)–donor(2)–acceptor molecule, MeOAn–ANI–NI, compound **19**, that mimics all of the primary spin-dependent charge separation and recombination dynamics of the photosynthetic reaction center. This makes it possible to use the same strategy as an entry point to a molecular switch based on photocontrollable spin dynamics. Transient absorption spectroscopy carried out on **19** in toluene determined the nature of the intermediates and the rate constants for intramolecular electron transfer between the electronic states in the energy level diagram displayed in Figure 6. At 295 K excitation with 420 nm, 130 fs laser pulses selectively excites the ANI chromophore within MeOAn–ANI–NI. The lowest excited singlet state of ANI accepts an electron from MeOAn with $\tau = 8$ ps. A subsequent dark electron transfer step with $\tau = 430$ ps forms the final radical ion pair, $^1[MeOAn^{+*}-ANI-NI^-]$, with a lifetime of 310 ns. Photoexcitation of **19** oriented in a solid liquid-crystal matrix results in the two broad electron paramagnetic resonance (EPR) spectra, shown at two orientations in Figure 7, with additional narrow lines superimposed at the center of the spectra. The broad spectra are due to a triplet state.

In all covalent electron donor–acceptor systems produced earlier, triplet states observed by EPR were formed via a spin–orbit intersystem crossing (SO-ISC) mechanism. Another possible mechanism of triplet formation is RP-ISC, mentioned above, which results from radical ion pair recombination, and which had been observed previously by time-resolved electron paramagnetic resonance spectroscopy (TREPR) only in bacterial reaction centers and in the green plant Photosystem I and II reaction centers. These two mechanisms can be differentiated by the polarization pattern of the six EPR transitions at the canonical orientations. In SO-ISC,

Figure 6. Energy level scheme for **19**. Internal conversion occurs in the fully charge-separated state to give the triplet. Charge recombination gives the T_1 state localized on the NI chromophore.

the three zero-field levels are selectively populated and this selectivity is carried over to the high-field energy levels. RP-ISC is also selective, but acts directly on the high-field triplet sublevels via singlet–triplet mixing $S-T^0$ (or $S-T^{\pm 1}$). Thus, SO-ISC results in mixed absorption (a) and emission (e) lines within a particular EPR transition, i.e., $T^i \leftrightarrow T^0$ ($i = \pm 1$), while in RP-ISC a mixed polarization pattern is impossible. Inspection of the triplet spectra (Figure 7) in the $B \perp L$ and $B \parallel L$ orientations shows that the polarization pattern of a,e,e,a,a,e can only be attributed to an RP-ISC mechanism, as found for reaction center proteins. This unique triplet state is localized on C, and exhibits zero-field splitting parameters identical to those obtained by direct observation of C itself.

In a subsequent study, Gust and co-workers synthesized and studied a compound **20**, consisting of a carotenoid and free base octaalkyl porphyrin (FBOAP) electron

Figure 7. a) Direct detection TREPR spectra of MeOAn-ANI-^{3*}NI in the nematic liquid-crystal mixture E-7 (Merck) at two orientations of the liquid-crystal director, L, taken 700 ns after a 420 nm laser pulse at 150 K. The narrow signal is an expansion of the radical pair signal. b) Numerical differentiation of the B ⊥ L spectrum.

donors, and a fullerene (C₆₀) electron acceptor [231]. In the fully charge-separated state this molecule decays exclusively to the triplet. The lifetime of the excited triplet state can be modulated by applying an external magnetic field at 77 K [111]. Excitation of the FBP with 416 nm laser pulses resulted in electron transfer to form the C-P⁺-C₆₀⁻ charge-separated state with $\tau = 10$ ps, and a quantum efficiency of unity. Hole transfer from the FBP to C competes with charge recombination and occurs with $\tau = 270$ ps and a yield of 0.14. This final charge-separated state decays exclusively to the carotenoid triplet state, ³C-P-C₆₀, with $\tau = 1.3$ μ s in the absence of a magnetic field. Application of a relatively weak magnetic field, B = 4.1 mT, resulted in a 50 % increase in the lifetime of the triplet state to $\tau = 2.0$ μ s. No effect was observed at ambient temperatures. Modulation of charge recombination on the picosecond time scale has also been observed in ferrocene complexes, albeit in a field of several Tesla [232].

Sato and co-workers presented the first example of the ability to optically change the magnetic field in a single crystal. The magnetic field is a macroscopic property, but the principle behind the switching mechanism is photoinduced electron transfer within the crystalline lattice. Sato and co-workers employed a Prussian Blue complex with the stoichiometry K_{0.2}Co_{1.4}[Fe(CN)₆] · 6.9 H₂O. It formed the rock-salt

crystalline lattice (21). The Curie temperature, T_c , below which long-range ordering of the electron spins results in the creation of a magnetic material, was 14 K. Illumination with 660 nm flashes of light raised this temperature to 19 K. The mechanism for switching of the magnetic properties is photoinduced electron transfer from the diamagnetic low-spin complex, $\text{Fe}^{\text{II}}-\text{CN}-\text{Co}^{\text{III}}$, to the high-spin $\text{Fe}^{\text{III}}-\text{CN}-\text{Co}^{\text{II}}$ electronic configuration. At 5 K this results in a doubling of the magnetic field strength. Furthermore, the lattice can be switched back to the low-spin diamagnetic state by the application of a second laser pulse at 450 nm. The overall time for both switching processes is on the order of several seconds, but this result is an important example of the ability to control macroscopic properties by switching on the molecular level. One can also envision the integration of switches based on spin control with this technology to yield an all-optical magnetic device.

(21)

The systems examined thus far have all been based on the propagation of positive or negative charge using consecutive laser pulses. Alternatively, it should be possible to base optical switches on the application of consecutive laser pulses to cause charge recombination. Electric fields can also have a profound effect on the lifetimes of charge-separated states. Debreczeny et al. demonstrated the all-optical control of an ion pair lifetime via the large, anisotropic, local electric field generated by a second ion pair [233]. The molecular tetrad (22) consists of zinc triphenylpor-

phyrin (Zn3PN) and phenyldimethylpyrromethene (PDP) electron donors and NI and PI electron acceptor groups. Selective excitation of PDP with 513 nm laser pulses resulted in electron transfer to form the $\text{Zn3PN-NI-PI}^--\text{PDP}^+$ charge-separated state with $\tau = 700$ ps and a quantum yield of unity. The lifetime of this charge-separated state is $\tau = 1.3$ ns. However, if a 416 nm laser pulse excites the tetrad 700 ps after the formation of the ion pair, its decay to the ground state is accelerated by an order of magnitude.

In further work, a similar system completely inhibited the formation of a second ion pair using the electric field of an initial ion pair. In compound **23**, Zn3PN and 9-(*N*-pyrrolidinyl)perylene-3,4-dicarboximide (pyr-PMI) are the electron donors, while once again NI and PI are electron acceptors [234]. Photoinduced electron transfer from Zn3PN to PI with 416 nm laser pulses occurs with $\tau = 27$ ps; however, if a 645 nm laser pulse is used to excite pyr-PMI, first this event is completely inhibited.

In addition to modulating the wavelength and timing of laser pulses, one can also perform photoinduced electronic switching by modulating the intensity of the laser pulses. This was demonstrated by O'Neil et al. using a molecule consisting of two free base triphenylporphyrin (FB3PN) electron donors covalently bound to either end of a perylene-3,4:9,10-tetracarboxylic diimide (PDI) electron acceptor, **24** [65].

Excitation of the FBP with 585 nm laser pulses results in single electron transfer to PDI, forming the state $\text{FB3PN}^+-\text{PDI}^--\text{FB3PN}$. When the intensity of the laser pulse is increased, both FBP moieties are excited, resulting in double electron transfer to PDI, forming the state $\text{FB3PN}^+-\text{PDI}^{2-}-\text{FB3PN}^+$. This effect is detected because the PDI anion absorbs at 713 nm, while the dianion absorbs at 546 nm. Thus, by modulating the laser intensity one can either singly or doubly reduce the perylene acceptor. This is possible because only 0.2 V separates the one- and two-electron reductions of PDI. Other molecules whose reduction potentials are closely spaced, such as terrylene, quaterrylene, and many metal complexes, should also display this behavior.

2.5 Energy Transfer Based Systems

Whereas electron transfer reactions that occur via a superexchange mechanism depend exponentially on the distance between electron donor and acceptor, Förster type, through-space (TS) energy transfer has a distance dependence of $1/r^6$. Thus, it is known to occur efficiently over much larger distances. Energy transfer is also known to occur via a Dexter, through-bond (TB) mechanism. For most of the rigidly linked systems described here, in which site-to-site distances are less than 20 Å, the Dexter mechanism is predominant. Within an antenna of mixed chromophores, energy transfer proceeds downhill in a site-to-site fashion until energy is localized on the chromophore with the lowest excited state energy. One advantage of using an antenna is that excitation is not site-specific, and absorption of a photon by any chromophore results in energy transfer to the same low-energy site. Fluorescence, nonradiative decay, electron transfer, or a combination of these processes follows energy transfer. Thus, employing light absorbers with large extinction coefficients allows versatility in the choice of electron donors or fluorophores. Designing systems for efficient light absorption across the visible spectrum that can transfer this energy to chromophores capable of converting the energy to chemical potential is an active area of research [132, 235, 236]. It also has applications for the design of efficient optical switching devices.

Many of the molecules discussed in the previous section are not highly robust and photodegrade rapidly under intense visible irradiation. However, switching errors are more likely to occur at low photon densities. A simple solution to this problem is to use a light-absorbing antenna that can efficiently transfer energy to the input chromophore. This greatly increases the lifetime of the devices, and in addition makes it possible to design an antenna that absorbs either at specific wavelengths, or across the entire visible spectrum. By a careful choice of chromophores energy transfer can alleviate many of the problems inherent in devising efficient robust all-optical switches employing electron transfer reactions. Many antenna complexes based on mixed metalloporphyrins have been studied [137, 138, 141–143, 146–148, 150, 237]. Porphyrins are often used because their electrochemical and spectral properties can be tuned by substitution of appropriate metals.

A synthetic system should meet several requirements in order for researchers to

learn useful information about the transfer of energy among the chromophores. It should be structurally rigid, soluble in organic solvents, and incorporate controlled metallation sites including free base and metalloporphyrins. Even so, there is no limit to the variety of architectures that can be constructed from arrays of covalently linked chromophores. Porphyrins are natural candidates for the creation of arrays with four-fold symmetry. Lindsey and co-workers synthesized a pentamer (**25**) consisting of four ZnP_s surrounding a central FBP [134]. This system undergoes energy transfer from the $^1\text{ZnP} \rightarrow ^1\text{FBP}$ with a quantum yield of approximately 90 % based on quenching of the ZnP emission. Further work from this laboratory has enabled the placement of eight light-harvesting chromophores about the periphery of a single free base or zinc porphyrin [144]. The phenyl rings of the

(25)

porphyrin are substituted at the 3 and 5 positions with ethynyl groups linked to boron dipyrromethene dye molecules.

Lindsey and co-workers also constructed macrocyclic square (**26**) and hexagonal (**27**) structures in which the alternating metallo- and free-base porphyrins form the subunits [143, 150]. The all free-base, zinc-, and magnesium-substituted arrays ($M_1 = M_2$) were synthesized as reference systems. In each system the dominant electronic mechanism was TB energy transfer; however, the rate decreased by 50 % between the square ($\tau_{TB} = 12$ ps) and hexagonal architectures ($\tau_{TB} = 17$ ps). This occurred despite there being one fewer chemical bond and a slight decrease in the center-to-center distance separating the chromophores. This effect was attributed to the change in substitution pattern from a *para* to *meta* linker. Thus, energy transfer in these architectures occurs via mediation of the conjugated linker groups, and not through the σ -bonded framework. Although these competitive rates are quite similar due to the proximity of the two chromophores, it should be possible to control energy transfer over greater distances on the basis of this effect.

(26)

(27)

The trigonal and tetrahedral macromolecules, **28** and **29**, respectively, are systems in which these ideas might be applied and were synthesized by Vauthey and co-workers [147]. Interestingly, these systems show significant contributions from both TB and TS energy transfer mechanisms. In **28** the ZnP to FBP distance is 35.5 Å along a shortest line, and 67.5 Å via the bonded pathway. The rate of ZnP → FBP energy transfer is $\tau = 62$ ps, and occurs primarily via a TS mechanism. Only when the bonded pathway becomes smaller, <45 Å, do the authors observe a shift to the TB mechanism. However, in compound **29**, where the interchromophore distance is 27 Å through space, and 32 Å through the bonded pathway, the TS mechanism

is still dominant. The TB mechanism is disrupted by the sp^3 -hybridized central carbon. This again demonstrates the need to give significant consideration to the electronic structure of the medium through which electronic communication must occur. The conjugation of the linker is especially important when energy and electron transfer events occur across large distances.

In **28** the array of chromophores is beginning to take on a dendritic type of architecture where the termini are capped with light-harvesting antennae. Recent work has demonstrated the construction of not only dendritic antenna complexes, but also of systems wherein the dendrimer itself is the light harvester [136, 139, 149]. The great advantage of using dendritic architectures is that the number of light-harvesting chromophores increases as 2^n for each additional generation. Unfortunately, this increase in photon absorption efficiency is countered by a decrease in energy transfer efficiency. The dendritic compounds **30** and **31** synthesized by Moore and co-workers again demonstrated the requirements for constructing efficient energy transfer dendrons. As before, the electronic structure of the intervening medium is crucial in designing an efficient system. Although **30** and **31** each contain

16 light-absorbing groups, the linking groups between absorber and collector are different. Compound **30** is a dendrimer with a simple fan-out macromolecular structure, while **31** contains localized regions of π -conjugation between the absorber and collector. This creates an energy gradient, which results in a directional energy flow, and is reflected in the rates of energy transfer. Energy transfer occurs with $\tau = 311$ ps in **30**, and despite the greater interchromophore distance the rate of energy transfer in **31** increases almost two orders of magnitude to $\tau = 5.3$ ps, with a yield of 98 %.

It is also possible to incorporate dendritic design motifs into polymeric systems. Sato and Aida have recently demonstrated the feasibility of constructing light-harvesting dendritic side chains on polymer chains of fluorophores [149]. The repeat

(30)

(31)

units of the dendrimer are 1,3,5-poly(benzyl) ether moieties. Polymers with dendritic side chains of between two and four generations were synthesized (**32**). The attachment of these groups to the poly(phenylene-ethynylene) polymer introduces a large absorption band at 278 nm in the ultraviolet region of the spectrum. Excitation in this region results in energy transfer to the polymer backbone with a quantum efficiency of unity, and is observed as fluorescence at 454 nm. In addition to acting as efficient light absorbers, the dendrimers also increase the fluorescent quantum yield. This is because the bulky side groups prevent interchain collisional deactivation. Similar types of dendrimers are readily applicable to polymers of the $[-D-A_1-A_n-]_n$ monomer type [238] both to improve solubility and to act as light-harvesting antennae.

(32)

It should be possible to employ intramolecular energy transfer reactions to perform logic operations similar to those discussed for intramolecular electron transfer. McGimpsey and co-workers synthesized and studied trichromophoric systems designed for a molecular shift register based on singlet-singlet and triplet-triplet energy transfer processes [239, 240]. Digital information is encoded as excitation

energy, which is propagated from one monomer unit to the next using consecutive laser pulses. The authors note that the chromophores in such a device would logically be arranged in order of descending excited-state energies. The series of chromophores ${}^1\text{A} < {}^1\text{B} < {}^1\text{C}$ would function so that excitation of A resulted in consecutive energy transfer steps becoming localized on C, similarly to the electron transfer scheme in Figure 5. Subsequently, a second laser pulse is used to excite ${}^3\text{C} \rightarrow {}^3\text{C}^*$, from which energy transfer to chromophore A on the next monomer unit occurs. Thus, data are encoded to the system in the singlet manifold, and propagate along the register in the triplet manifold. The use of singlet–singlet and triplet–triplet energy transfer also allows for potential control of relative rates within these systems with applied external magnetic fields, as discussed earlier.

Compounds **33** and **34** were designed to test this hypothesis using monomeric model compounds. A biphenyl (BP) was employed as a light absorber, held rigidly between phenanthrene (PE) and naphthalene (NP) chromophores using ester and adamantyl linkers in **33** and **34**, respectively. The saturated adamantyl bridge lowered the excited-state energies of each chromophore by approximately 0.1 eV; however, the driving force for energy transfer remained constant between the two systems. Excitation of the BP moiety within **33** and **34** with a 226 nm flashlamp resulted in the formation of the $\text{PE}-{}^1\text{BP}-\text{NP}$ state. The energy level diagram for this system is displayed in Figure 8. A series of singlet–singlet energy transfer steps, k_1 and k_2 , resulted in localization of the excited-state energy on the phenanthrene. In each system k_1 occurred with $t < 30$ ps; however, the rate for k_2 differed significantly: $k_{2,33} = 2.5 \times 10^8 \text{ s}^{-1}$, while $k_{2,34} = 2.5 \times 10^6 \text{ s}^{-1}$. This is due to the differences in coupling for the through-bond energy transfer process. Intersystem crossing within the phenanthrene yielded the ${}^3\text{PE}-\text{BP}-\text{NP}$ triplet excited state.

Excitation within the triplet manifold of PE is possible because of its $\text{T}_1 \rightarrow \text{T}_n$ absorption near 500 nm. Application of a second laser flash at 488 nm resulted in

Figure 8. Energy level scheme for **33** and **34**. Excitation with 226 nm light populates 1^*BP , which undergoes efficient energy transfer to 1^*PE and 1^*NP . Subsequent energy transfer and intersystem crossing populate the triplet state of the phenanthrene, 3^*PE . Excitation to the 3^{**}PE state with 488 nm light results in stepwise energy transfer to 3^*BP and 3^*NP , the latter of which acts as an energy well.

triplet–triplet energy transfer to 3^*BP , k_3 , followed by energy transfer both to 3^*NP , k_5 , and back to 3^*PE , k_4 . The ratio $k_4/(k_4 + k_5)$ determines the efficiency of the switching operation. For these systems the switching efficiency was approximately 50 %; however, tuning the coupling and energetics of the chromophores could optimize this.

Thus far we have examined systems which were designed for the absorption of energy by one chromophore, transferring the excitation, and finally dissipating this energy via emission by some other chromophore. It is also possible to modulate this emission and create a molecular switch based on competing routes of energy transfer, one of which is nonradiative. An example of such a switch employing energy transfer in porphyrin arrays is an optoelectronic gate synthesized by Lindsey and co-workers [148]. It consisted of three porphyrins and a light-absorbing dye in a linear or branched arrangement (compounds **35** and **36**); their operation is identical. The branched design, **36**, consists of a tri-substituted zinc porphyrin (ZnP) with a boron dipyrromethene dye (BDPY), and magnesium and free-base porphyrins (MgP and FBP, respectively) on its periphery. The FBP *para* to the BDPY has the lowest-energy excited state, and is highly fluorescent. A HOMO/LUMO scheme for this array is shown in Figure 9. Excitation of the BDPY with 485 nm light initiates

a stepwise energy transfer. The energy becomes localized on the FBP and is dissipated radiatively as fluorescence centered at 650 nm. The quantum yield for the total process is approximately 0.8 in both the linear and branched architectures. Activation of a nonradiative decay pathway within the system can modulate this emission. The MgP has the lowest oxidation potential (${}^{+1}E_{1/2} = 0.34$ V vs. SCE) and a vacancy in its HOMO can be easily created by electrochemical or chemical

Figure 9. Energy level scheme for **35** and **36**. Excitation with 485 nm light initiates a series of energy transfers which localizes the excitation onto the chromophore with the lowest-energy excited state. In the neutral state (solid), this is the FBP. Electrochemical oxidation of MgP lowers its excited state energy (dash) and activates a nonradiative decay pathway.

oxidation. For this experiment iron perchlorate, $\text{Fe}^{\text{III}}(\text{ClO}_4)_3$, was used as the chemical oxidant. Once oxidized, energy transfer occurs to the MgP^+ , which has low-lying absorptions indicative of a manifold of low-energy singlet–singlet transitions. These are nonradiative, and thus no emission is observed from the monocationic species. Furthermore, the fluorescence signal was fully restored by returning to the neutral species via addition of triethylamine or electrochemical reduction. This system demonstrates the ability to modulate energy transfer in large arrays; however, the ON/OFF switching of fluorescence is limited by diffusional processes which are relatively slow compared to the energy transfer events [66].

A tri-chromophoric system (**37**) studied by Wang and Wu switches between energy and electron transfer pathways in a single molecule via proton binding [106].

(**37**)

Anthracene

Piperazine

Chalcone

In **37**, absorption of near-ultraviolet light by the anthracene results in quenching by electron transfer from a nearby piperazine. Bound to the other side of the piperazine is a chalcone moiety, an α,β -unsaturated carbonyl group, which has a lower-energy excited state than the anthracene. When H^+ ions are added to solution, electron transfer is quenched via H^+ binding at the piperazine site, and energy transfer can proceed from the anthracene to the chalcone. There are also examples of electron transfer controlled by reversible proton binding in ruthenium complexes [241, 242]. While these systems are highly efficient, they rely upon the slow processes of diffusion and ion binding in solution to modulate the much faster electron transfer reaction.

Gust and co-workers designed a synthetic antenna reaction center capable of undergoing energy transfer followed by electron transfer [146]. Four ZnP chromophores arranged in a cross are covalently linked to an FBP electron donor and C_{60} electron acceptor, **38**. Excitation of a ZnP results in energy transfer, $\tau = 240$ ps, to the FBP with a quantum yield of 0.69. The excited state of the FBP decays exclusively via electron transfer, $\tau = 3$ ps, giving rise to the charge-separated ZnP_4^-

FBP⁺-C₆₀⁻ state which has a lifetime of $\tau = 1$ ns. The authors discuss several parameters that determine the efficiency of energy transfer in light-harvesting antennas. The choice of metal for substitution in the porphyrin is key in determining the rate and yield for energy transfer because the metal exercises control over both the electrochemical properties and excited-state lifetime. As stated previously, a through-bond energy transfer mechanism is dominant for most antenna complexes, and the choice of linkage is thus critical in determining electronic coupling between sites. This includes factors such as substitution site and steric hindrance in addition to site-to-site distance and bond type. Several small, fast, and highly efficient energy transfer steps are likely to be much more efficient than a single one-step energy transfer.

One of the foremost concerns in this field is the leap to be made from studying isolated complexes to the synthesis of large assemblies that will retain the characteristics of single molecules. The synthesis of large, covalently linked, light-harvesting and switching assemblies becomes increasingly complex as more chromophores and redox-active units are added. It is clear that many of the design considerations that apply to the single-molecule level are not suitable for the synthesis of macromolecules. Thus, it is desirable to construct architectures via self-assembly [243–250] or other techniques [251] which have exceedingly high yields and arrange themselves with minimal defect sites. Dendrimers [96, 252–257], polymers [258–261], membranes [262–266], and zeolites [267–275] have been employed as supports for the construction of well-defined supramolecular arrays. However, it may be unnecessary to construct entire arrays in which the local environment of each subunit is rigorously controlled.

Recent work has demonstrated the deposition of consecutive nanometer-thick thin films of light-harvesting and redox-active molecular subunits to create a layered structure capable of stepwise energy and electron transfer [276]. The light-harvesting chromophores coumarin (**39**) and fluorescein (**40**) are synthesized as ionic polymers of poly(allylamine hydrochloride) (**41**). They are deposited sequentially and absorb light across a large portion of the visible spectrum and funnel it to a palladium(II) tetrakis(4-sulfonatophenyl)porphyrin (**42**). This chromophore has a long-lived excited triplet state, and can transfer an electron to an acceptor in the next layer. In this case the electron acceptor is viologen-substituted polyvinyltoluene (**43**).

A key aspect of this system is the insertion of semiconductor layers between the layers of chromophores. Local control is exerted over the network of covalent bonds, but there is no rigorous control over the local environment during film for-

(41)

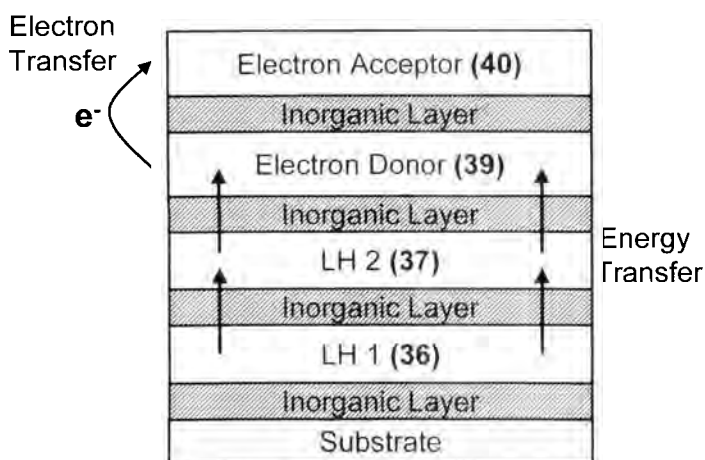

Figure 10. Schematic representation of the organic–inorganic solid-state hybrid synthesized by Mallouk and co-workers [276]. Absorption of a photon by any of the organic layers results in energy transfer to the electron donor layer. This initiates an intermolecular electron transfer reaction. Interestingly, the yield of both energy and electron transfer can be modulated by changing the electronic characteristics of the inorganic semiconductor material.

mation. The inorganic spacers ensure that each layer maintains a homogeneous distribution of chromophores, and that there is no interlayer migration. No covalent bonds link any of the redox-active chromophores. The semiconductors both increase the yield and the rate of electron transfer from the excited state of the donor and inhibit the back electron transfer reaction from the acceptor. These layers consist of anionic $\text{Zr}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$ (α -ZrP) or HTiNbO_5 sheets. Figure 10 shows the scheme for this assembly. Energy and electron transfer occurred with quantum yields of 0.47 and 0.61 in the α -ZrP and HTiNbO_5 spaced assemblies, respectively. The rate of energy and electron transfer in any of these systems is an ensemble average of all sites within the layered assembly, and thus there is no single rate for any of the processes in the assemblies. Nonetheless, in addition to the increased quantum yield, assemblies constructed with the HTiNbO_5 spacer exhibit a long-lived charge-separated state component not observed in the α -ZrP spaced assemblies, $\tau = 900 \mu\text{s}$. While there is still much to be learned from the study of multichromophore arrays, this synthetic approach appears to hold much promise for the creation of organic–inorganic hybrid solid-state devices. This research also lends credence to the idea that the three-dimensional location of individual components within a molecule-based computer need not be rigorously controlled to take full advantage of their photochemical properties.

(43)

2.6 Conclusions and Future Prospects

The creation of ever more complex systems designed to exhibit single-molecule switching is an ongoing process. There are still many hurdles to cross before optical molecular switches are integrated with other components to build all-optical computing devices. The synthesis of large arrays of molecule-sized switches into a network capable of processing information is a major challenge. Whereas covalent attachment schemes can be used to test a variety of switch concepts, ultimately a molecular self-assembly strategy is necessary to carry out organization of these elementary units into large, working arrays. Much of the current research on molecular switches is oriented toward the implementation of individual components operating in a solid, organized matrix. Surface attachment and/or three-dimensional order induced by incorporation into a crystalline matrix may be necessary to achieve full functionality for such systems. However, our understanding of membrane-based switches in living cells and biological regulators points toward applying basic thermodynamic principles to arrange appropriately functionalized chromophores noncovalently using a potential gradient.

Addressing molecular switches remains a problem as well. The use of diffraction-limited focused light pulses provides a useful start, but subdiffraction optical techniques need to be improved and implemented to transfer information into and out of these molecular arrays. At present near-field optical techniques are relatively slow, so that although they provide better spatial resolution, the speed of information access is somewhat limited.

Finally, the fundamental quantum mechanical challenges of using molecules themselves to store and process information needs to be more fully explored. While the fundamental limitations dictated by the Heisenberg uncertainty principle place stringent criteria on such information processing, the intrinsic properties of quantum systems may be exploited for molecule-based computation. The ability of quantum systems to function as coherent superpositions of states [277] may make it possible to design molecules that take advantage of these properties to implement quantum computation schemes [278–280]. The future of this area is quite promising, especially when one considers the vast possibilities provided by molecular design and synthesis coupled with utilization of the numerous photophysical properties of molecules.

3 Photonic Wires Containing Metal Complexes

Luisa De Cola and Peter Belser

3.1 Introduction

The control of the electronic properties in molecular systems has acquired a growing importance in chemistry, especially in the field of molecular electronics and nanotechnology in connection with electronic and photonic applications [1–9]. The burgeoning of supramolecular architectures [10–16] that could perform functions that the simplest systems do not [17–20], the need to realize nanosized systems to fill the gap between the molecular and the macroscopic world, and the development of new synthetic strategies have contributed strongly to the design and realization of rods and wire-type systems [21–25]. Many organic conjugated oligomeric systems [4, 23] and conductive polymers [2, 3, 9] have been described and the possibility of tailoring their electronic and structural properties to accomplish a desired function and use them in optoelectronic devices has been described by several authors [4, 9]. Despite the increasing number of rod- and wire-type molecules, the assembly of such molecules with metal complexes units to build up multicomponent systems, the simplest being dinuclear complexes, is rather limited [18, 24–27]. Many dinuclear complexes have been studied with the aim of obtaining quantitative statements on the motion of charge or excitation energy along one or another type of rod. The role played by σ or π symmetry orbitals, the effect of the substituents on the peripheral ligands, and the difficulties associated with a localized vs. delocalized model in highly conjugated species surely need more investigation. We have tried in this chapter to collect some, in our opinion representative, examples of “rigid” systems containing metal complexes covalently linked through a bridging ligand. We have selected some “nonconductive” species and compare their properties with some that show a conductive or “wire-type” behavior. We have restricted our discussion only to dinuclear compounds containing Ru, Os, or Rh complexes as electron and/or energy donor/acceptor (D/A) moieties. We have divided the compounds according to the nature of the bridging ligand and we have included, at the

Figure 1. Schematic representation of a simple dinuclear compound.

end of each section, a table containing the most important photophysical data, related to species where photoinduced processes were observed.

3.2 Choice and Assembly of the Components for Photoactive Systems

In order to have a rod-type system where photoinduced energy transfer or electron transfer processes can occur, great attention must be devoted to the separated components and to the way they are connected [24, 26–29]. The simplest system conceivable for the occurrence of a photoinduced process, a dyad, is depicted in Figure 1.

As shown schematically, we can recognize three important elements in the construction of a dyad: the donor and acceptor sites that in our discussion are metal-based units, the connectors, and the bridging ligand. Many multicomponent systems incorporating photoactive and electroactive units based on metal transition complexes have been constructed [24, 26–28], especially with the attractive electrochemical and excited-state properties of $M(N-N)_3^{n+}$ or $M(N-N-N)_2^{n+}$ complexes, where M is a metal ion of the second or third transition rows, $N-N$ is a bidentate bpy-type or phen-type ligand (bpy = 2,2'-bipyridine, phen = 1,10-phenanthroline), and $N-N-N$ is generally a tpy-type ligand (tpy = 2,2':6',2''-terpyridine). Extensive investigations performed on $[Ru(bpy)_3]^{2+}$ and $[Os(bpy)_3]^{2+}$ and related complexes [12, 26, 27, 30–32] have shown that:

- 1) their high-intensity absorption bands in the 250–300 nm spectral region are due to spin-allowed ligand-centered (LC) transitions;

- 2) their absorption bands in the 400–550 nm region are due to spin-allowed metal-to-ligand charge-transfer (MLCT) transitions;
- 3) for the compounds of the heavier (Os) metal, spin-forbidden MLCT bands can also be seen in the 550–700 nm region;
- 4) luminescence takes place from the lowest-energy triplet MLCT excited state;
- 5) the luminescent excited state is very rapidly populated with unit efficiency regardless of the excitation wavelength.

At room temperature in fluid solution $[\text{Ru}(\text{bpy})_3]^{2+}$ and $[\text{Ru}(\text{phen})_3]^{2+}$ exhibit a strong and long-lived luminescence (τ of the order of 10^2 – 10^3 ns) [30, 31]. A different behavior is shown by terpyridine compounds, which offer important geometrical advantages (the possibility of constructing linear and rigid arrays) but poor emitting properties [33]. In fact $[\text{Ru}(\text{tpy})_2]^{2+}$ is very weakly luminescent (τ ca. 0.25 ns) [33] because of the low energy of the metal-centered states, ^3MC , which can be thermally populated from the luminescent $^3\text{MLCT}$ state. Besides ruthenium and osmium, other luminescent metal units have been used to construct multinuclear compounds. $\text{Re}(\text{I})$ diimine complexes of general formula $\text{ReL}(\text{CO})_3\text{X}^+$ exhibit luminescence at room temperature which is usually due to $d\pi \rightarrow \pi^*$ ($^3\text{MLCT}$) or $\pi \rightarrow \pi^*$ (^3LC) transitions, but these will not be discussed in this chapter. $\text{Rh}(\text{III})$ and $\text{Ir}(\text{III})$ complexes containing polypyridine or cyclometallating chelating ligands $\text{N}-\text{C}^-$ have also been used in the construction of multinuclear systems and some examples will be given.

In order to assemble these metal-containing building blocks it is necessary to have a connection between the metal units. Such a structural component, the bridging ligand, should contain sites able to coordinate the metal center, and suitable spacers in order to control distance and orientation of the chromophores (see Figure 1). The main requirements for the bridging ligand are therefore: control of the overall geometry, rigidity, and length modulation. The first two requirements have been achieved for several systems, but a modular nature of the bridging ligand is often difficult to attain for synthetic reasons, solubility being the most important [11, 22, 27]. In order to provide a way of varying the distance and the electronic interaction between the two chromophores, the bridging ligand must contain spacers, conjugated or saturated molecules that can be modular units. With such an arrangement it is clear therefore that one can tune the rates of the energy and electron transfer processes with an appropriate choice of components. It is important to notice, however, that even the use of rigid spacers, such as polyphenylenes or saturated molecules, provides in some cases a fixed metal–metal distance, but does not prevent conformational effects. In fact rotation around formally single bonds will confer some conformational freedom, and if the intercomponent interaction proceeds via the π system of the bridge, the tilt angle between the spacers can have relevant consequences for metal–metal interactions and for electron transfer rates. Therefore the connections between the spacers and/or the chelating sites is another factor that should not be neglected.

Another important consideration concerns the peripheral ligands. Figure 2 shows the peripheral ligands that are employed in the systems discussed here.

Figure 2. Peripheral ligands and their abbreviations.

In many dinuclear compounds the lowest excited states involve the bridging ligand, since very often the lowest LUMO is localized on the more delocalized π system of the bridge. Therefore in such cases the peripheral ligands play only a minor role in the excited-state properties of the complexes. On the other hand, when the peripheral ligands have excited states lower in energy than the bridging ligand, upon light excitation the lowest MLCT will involve the ancillary ligands and the distance between the two chromophoric groups will be greater (for an example see Section 3.5.3). This consideration allows the construction of dinuclear compounds in which the lowest excited state can involve either the bridging or the peripheral ligand, depending on the substituents (electron donor or acceptor groups) on the ancillary ligands. A similar situation has been observed in the case of electron-rich bridging ligands for instance pyridyltriazole ligands, in which the lowest excited state is often localized on the peripheral ligands [34].

3.3 Intercomponent Photoinduced Processes

For a simple dinuclear compound D–S–A the photoinduced energy and electron transfer processes are represented schematically in Figure 3.

Since theoretical treatment of photoinduced processes may be found in recent review articles and books [35–47] and will be treated in other chapters, we recall only a few fundamental features below.

In an absolute rate formalism, the Marcus model [41a], the rate constant for an electron transfer process can be expressed as:

Figure 3. Schematic energy level diagrams for photoinduced energy transfer (left) and electron transfer (right) processes.

$$k_{\text{el}} = \nu_{\text{el}} \exp(-\Delta G_{\text{el}}^{\ddagger}/RT) \quad (1)$$

where ν_{el} is an effective frequency for nuclear motion, and $\Delta G_{\text{el}}^{\ddagger}$ is the free activation energy. $\Delta G_{\text{el}}^{\ddagger}$ depends on the driving force of the reaction and on the reorganizational energy λ , as expressed by the Marcus equation [41a]:

$$\Delta G_{\text{el}}^{\ddagger} = (\lambda/4) \left(1 + \frac{\Delta G^{\circ}}{\lambda} \right)^2 \quad (2)$$

Dealing with dinuclear metal complexes, the electronic interaction (often through-bond interaction) is strongly dependent on the length, electronic nature and geometry of the bridging ligand. The role of the bridging ligand in enhancing the electronic coupling between the two chromophoric groups in a multicomponent system has been described in terms of superexchange theory [35–37, 48–53]. This theory provides an approach where overlap between the metal-based components is mediated by overlap with the orbitals of the bridging ligands (through-bond interaction). The parameters which govern the extent of the interaction are therefore the orbital overlap and the energy gap between the relevant metal orbitals and LUMO/HOMO orbitals of the bridging ligand. In the case of modular bridging ligands constituted by a different number of spacers, an exponential dependence of the

electronic coupling on the number of spacers must be considered [35, 37, 51–53]:

$$H = H(0) \exp - [(\beta/2)(r - r_0)] \quad (3)$$

where r is the (through-bond) length of the spacer, r_0 is the distance between the donor and acceptor components without the spacer, $H(0)$ is the corresponding electronic coupling value and β , the attenuation factor, is a term which contains the interactions between the spacers. Most of the above-mentioned parameters and the rates for the electron transfer processes can be obtained by photophysical measurements [54].

The energy transfer processes can occur by two mechanisms: the Förster-type mechanism (through-space) [55], based on coulombic interactions, and the Dexter-type mechanism (through-bond) [56], based on exchange interactions. The energy transfer rate constants according to the Förster and Dexter treatments can be evaluated by Eqs. (4) [55] and (5) [56], respectively:

$$k_F = \frac{8.8 \times 10^{-25} K^2 \Phi}{n^4 \tau r^6} J_F \quad (4)$$

$$k_D = \frac{4\pi^2 H^2}{h} J_D \quad (5)$$

where H is the intercomponent electronic interaction energy, K is a geometric factor, Φ and τ are the luminescence quantum yield and the lifetime of the donor, respectively, n is the refractive index of the solvent, and J_F and J_D , according to the two different theories, are the overlap integrals between the luminescence spectrum of the donor, and the absorption spectrum of the acceptor, respectively [55–58].

In the weak-interaction limit, the exchange mechanism can be described in terms of thermodynamic quantities, according to a classical approach which parallels that for nonadiabatic electron transfer (see Eqs. (1) and (2)) [59–63].

The free energy change, ΔG° , for the energy transfer reaction can be expressed by the difference between the zero-zero spectroscopic energies of the donor and the acceptor excited states, which can be estimated from the luminescence band maxima of the reference complexes taken at 77 K [57, 64, 65].

Both through-bond and through-space transfer mechanisms can operate in donor-acceptor systems. Very often these mechanisms occur competitively and in some cases they can practically add to each other; their relative contributions are difficult to evaluate.

An evaluation of the rate constant of the energy transfer process can be obtained from Eqs. (6a) and (6b):

$$k_{en} = 1/\tau^\circ (I^\circ/I - 1) \quad (6a)$$

$$k_{en} = 1/\tau - 1/\tau^\circ \quad (6b)$$

where I° and τ° are the luminescence intensity and lifetime, respectively, of the species that can be quenched, the donor component, and I and τ are the residual luminescence intensity and lifetime after quenching. Long-lived excited states and

high luminescence quantum yields are preferred in the study of photoinduced processes and for the construction of supramolecular photochemical systems. This is simply due to the fact that short-lived excited states will decay to ground states before the desired reaction is accomplished.

In dinuclear metal complexes electronic interactions between the mononuclear components may range from very strong (with profound changes in the absorption spectrum on passing from mononuclear to dinuclear species) to very weak (with almost equal properties for separated and bridged units), depending on the type of bridge. If the interaction between the two metal-based units (for instance, polypyridine units $M(L)_n^{n+}$) in a dinuclear or multinuclear compound are weak, the following results are usually obtained:

- 1) the absorption spectra in the visible region of the homodinuclear $[M(L)_n-LSL-M(L)_n]^{n+}$ (LSL = a bridging ligand constituted by a spacer S and two chelating sites L) species are practically identical to those of the corresponding $[M(L)_n]^{n+}$ model compound;
- 2) the absorption spectra in the visible region of the heteronuclear complexes $[M(L)_n-LSL-M'(L)_n]^{n+}$ are practically identical to those of 1:1 mixtures of their corresponding homodinuclear $[M(L)_n-LSL-M(L)_n]^{n+}$ and $[M'(L)_n-LSL-M'(L)_n]^{n+}$ parent compounds;
- 3) the emission maximum, lifetime, and (in the homodinuclear complexes) quantum yield of the phosphorescence band of each $[M(L)_n]^{n+}$ unit are unaffected by the length of the spacer and by the nature of the metal contained in the $[M'(L)_n]^{n+}$ unit.

It should be recalled, however, that even an interaction of a few cm^{-1} (which cannot be noticed in spectroscopic experiments) may be sufficient to cause inter-component energy transfer or electron transfer processes. As already mentioned, the nature and length of the bridging ligand can contribute strongly to the rate of the photoinduced processes. Many compounds have been labeled wire molecules, but in most cases the wire-type behavior could not be observed. However, one should first define what is a molecular wire and what are the expectations for such a system.

3.4 What is a Molecular Wire?

One of the most important components of an integrated electronic system is the connection between the active units: the so-called wire. As in the macroscopic world, a (molecular) wire is a (molecular) structure that transmits a signal between two termini. The wire can transfer excitation energy or move electron or hole charges [3, 5, 66]. In our chapter we will refer to systems in which the charge or energy transport is due to a photoinduced intramolecular process and the molecular wire is indeed the bridging ligand between the donor and the acceptor sites. A molecular system, in order to behave as a wire, must have some structural features such as rigidity and modularity, and when used as a bridging ligand, in a donor–acceptor

Figure 4. Schematic formula of the molecular wire reported by Wasielewski et al. [66].

system to perform photoinduced processes, this behavior should be independent of distance [3, 5, 24, 66, 67]. Such ideal behavior is hard to achieve for molecular wires, and in most of the compounds investigated an exponential decay of the rate of photoinduced processes has been observed. The growing interest in this field has led to a search for systems in which long-distance energy and electron transfer can be achieved, the rates of the photoinduced processes being fast ($k > 10^9 \text{ s}^{-1}$) and relatively independent of the length of the system. For example, Wasielewski and co-workers have recently reported a weak length dependence in highly conjugated systems [66]. In their system, schematized in Figure 4, the molecular wire behavior can be attained when there is an energy match between the donor and the bridge components; such requirements are indeed achieved in their multicomponent system when the bridging ligand contains more than three spacer units.

Also in metal-containing systems several attempts have been made to design systems that could show a wire behavior (see, for example, Refs. [24, 25, 67–70]). The use of metal complexes as D or A units is particularly attractive since the photo-physics and excited-state redox properties of many transition metal chromophores are tunable and therefore a tailor-made system can be obtained. It is interesting to recall that for metal complexes the excited state responsible for energy and electron transfer is often the lowest-lying triplet state, and that the photostability of such building blocks is generally very high [31, 71]. We will discuss some of these dinuclear systems, which we have divided into families depending on the type of the bridging ligand.

3.5 Systems Containing Saturated Spacers

Some dinuclear complexes, **1–10** [24–28, 38, 72–89], containing rigid saturated spacers are shown in Figure 5 and, for the species for which photoinduced processes have been observed, the photophysical properties are reported in Table 1.

Figure 5. Dinuclear complexes containing saturated rigid bridging ligands.

^a abbreviations are defined in a separate section in the text, ^b E_m , Emission maximum.

We have prepared and investigated several systems containing saturated molecules, **3–8** [20, 27, 28, 38, 77–81, 83–86]. In our investigations the distance between the metal centers ranges from 16 to 21 Å. In the dinuclear compounds **5–8**, where the two metal units are connected to the spacer by double bonds, or in systems **9**, we can really talk about rigid rod-like molecules. The electronic coupling is extremely small (a few wavenumbers), but both photoinduced energy and electron transfer processes are still fast enough to compete efficiently with the decay of the excited state of the ruthenium moiety (see Table 1). In donor–acceptor systems bridged by saturated species, large attenuation factors have been reported for such groups ($\beta = 0.85 - 0.95 \text{ Å}^{-1}$) [90], and we can conclude that such spacers behave as insulating units. Rigid homometallic dinuclear complexes containing similar saturated spacers in the bridging ligand have been reported by Paddon-Row [21, 52, 76, 87] and Keene [73, 88, 89]. In complex **9a** [76] a similar rate constant for intramolecular energy transfer has been observed and a through-bond (Dexter-type) mechanism was postulated (see Table 1).

3.6 Systems Containing Conjugated Spacers

A π -conjugated system is a molecule along the backbone of which occurs a continuous path of carbon atoms or heteroatoms, each carrying a p atomic orbital. The determination of the electronic structure of conjugated systems and their properties in terms of energy, electron and hole transport is very difficult. Electron correlation effects must be taken into account and the strong connection between, and mutual influence of, the electronic and geometric structures should be evaluated [91].

π -conjugated molecules, such as polyalkenes, polyalkynes, poly(*p*-phenylene) (PPP), poly(phenylene-vinylene) (PPV), and poly(phenylene-ethylene) (PPE), (see, for instance, Refs. [2, 4, 9, 23, 92]) have been extensively studied since they possess unique geometrical, optical, and electronic properties. They can be prepared as defined oligomers with discrete numbers of repetitive units or as conjugated polymers. Their colors and optical properties can be changed upon introduction of substituents or side chains [4]. Introduction of solubilizing side chains has been an essential choice in order to achieve the solubility necessary to build up large oligomers. Their behavior and applications are the focus of this chapter; we shall discuss their use as bridging ligands (BL) in donor (D)/acceptor (A) systems (D–BL–A), and their molecular wire behavior.

3.6.1 Polyene-bridged Bimetallic Compounds

Despite the great number of oligoene systems and their use as molecular wires in donor–acceptor compounds containing organic fragments [22, 23], only a few dinuclear compounds containing oligoene oligomers as bridging ligands have been synthesized and investigated (see Figure 6: compounds **11–16**) [93–98].

Figure 6. Dinuclear complexes containing oligoenes as bridging ligands.

Most of them, however, are monometallic species for which no information about photoinduced processes has been reported. Due to strong electronic coupling between the two metal units, the compounds containing polyene-bridged bis(bipyridine) exhibit large differences in electrochemical and photophysical behavior between the monometallic and dinuclear complexes. Lehn and co-workers [94] have reported for compounds **13** an electronic coupling matrix of 140 cm^{-1} over a distance of 24 \AA . An attenuation factor β of 0.06 \AA^{-1} has been calculated [94]. For the dinuclear complexes **11** [95], **12** [96, 97], and **16** [95] the authors reported low-lying emitting states with rather long excited-state lifetimes. The assignment of the excited state was not clear, but mixing of the $^3\text{MLCT}$ levels with the close triplet Intra-Ligand (^3IL) states of the bridging ligands was suggested [96]. Hosseini and co-workers have recently reported [75] the synthesis of the complexes **15** and their photophysical properties are under investigation [98].

Figure 7. Dinuclear complexes containing oligoynes as bridging ligands.

3.6.2 Oligoyne-bridged Bimetallic Compounds

An important class of conjugated bridging ligand comprises those containing $\text{C}\equiv\text{C}$ as spacers. Oligoynes can be easily accessible bridging ligands; however, due to the flexibility and poor stability and solubility of the longer oligomers and complications arising with increasing chain length, lowering of the triplet energy and decrease of the redox potentials of the polyalkyne, their use has been restricted to short oligoyne linkers. The short systems have quite a good thermal and photochemical stability, and can be easily functionalized in the terminal CH group. They have been used as bridging ligands to construct inorganic dyads such as the complexes **17–20** [67c, 70, 99–109] reported in Figure 7.

In general these bridging ligands are good electron conductors, but worse than oligoenes, presumably because of the large bond-length alternation between the single and the triple bonds. The synthesis of the corresponding dinuclear compounds has been achieved by normal procedures, reacting the bridging ligand with the metal complex precursor [67c, 70, 99–105], or more recently by a direct coupling of two metal-based components, a strategy developed by Tor and co-workers [106–109] (Scheme 1). In such a way the synthesis of heterometallic complexes can be achieved in one coupling step using complementary functional groups on each metal fragment.

Most of the systems shown in Figure 7 have been obtained by Ziessel and co-workers, who have carried out detailed investigations on their photophysical properties and intramolecular photoinduced processes [67c, 70, 99–103, 110, 111]. Some

Scheme 1. The reaction used by Tor and co-workers to prepare oligoyne-bridged homo- and heteronuclear compounds (see text).

of the results are summarized in Table 2. The general behavior of these dinuclear compounds is consistent with the assessment that oligoyne spacers are electronic conductors at the molecular level. In complexes **18d**, for example, even though the intramolecular energy transfer process is only slightly exoergic, $\Delta G = -0.11$ eV, a very fast rate has been observed (see Table 2) [99]. The electronic coupling matrix element has been estimated to be ca. 12 cm^{-1} and so fast a process has been attributed to a Dexter-type energy transfer mechanism.

A similar result was obtained for complexes **18b** and an attenuation factor $\beta = 0.17\text{ \AA}^{-1}$ was reported [99]. It should be pointed out that for the terpyridine complexes the presence of the second metal unit increases the excited-state lifetimes. Such an observation can be rationalized by the presence of extensive electron delocalization in these dinuclear compounds. This desired improvement in the photo-physical properties precludes, however, a clear description of the electronic excitation path and of the distinction between donor, bridging ligand, and acceptor site. The authors suggested that the electron delocalization could be reduced by introduction of small insulators into the carbon bridge which could also help to decrease the direct participation of the bridge in subsequent photochemical or redox processes involving the active terminal chromophores. The introduction of a phenyl ring between a polypyridine ligand and a polyalkyne spacer, in complexes **20** [99–101], causes a dramatic reduction in the electron delocalization. A similar behavior has been observed by insertion of a Pt(II) bis-*s*-acetylide complex, or by the incorporation of chelating heterocycle unit for this purpose [67c, 70, 99, 101, 105, 110]. In the last case the possibility of tuning the energy levels of the bridging ligand upon complexation seemed quite appealing (see Section 3.7).

Figure 8. Dinuclear complexes containing *p*-phenylene oligomers as bridging ligands.

3.6.3 Phenylene-bridged Bimetallic Compounds

Oligophenylene rods [92, 112] have attracted much interest as spacers [113], because of their thermal and photochemical stability, and their interesting tunable photo-physical properties. Until recently their use as bridging ligands was limited to species containing only one or two phenylene units (see compounds **23–26**, Figure 8) because of synthetic difficulties related to solubility problems [24, 33, 74, 97, 114–117].

This difficulty has recently been overcome by Schlüter and co-workers, who reported oligomers containing up to 16 phenylene units bearing solubilizing groups

in good yields [11, 118–120]. Using this strategy we have recently reported [69] homodinuclear and heteronuclear complexes containing the bridging ligand **23**. In heterodinuclear Ru23Os compounds, besides complete quenching of the fluorescence of the oligophenylene spacers, a quenching of the phosphorescence of the $[\text{Ru}(\text{bpy})_3]^{2+}$ chromophoric unit and a parallel sensitization of the phosphorescence of the $[\text{Os}(\text{bpy})_3]^{2+}$ chromophoric unit were observed, indicating the occurrence of electronic energy transfer (see Figure 9). Such an observation was clearly confirmed by the observed rise time at 77 K (Figure 9b).

The rate of the energy transfer process from the $[\text{Ru}(\text{bpy})_3]^{2+}$ to the $[\text{Os}(\text{bpy})_3]^{2+}$ unit is practically independent of temperature and decreases with increasing length of the oligophenylene spacer (see Table 3) [69].

It was shown that such an energy transfer process takes place via a Dexter-type mechanism (superexchange interaction) with an attenuation coefficient of 0.32 \AA^{-1} . It is interesting to notice that the planes of the rings of adjacent phenylene moieties in *p*-polyphenylenes form an angle of $20\text{--}40^\circ$ because of the steric repulsion between the *ortho* hydrogens [121–124]. Substitution of the rings leads to an increase in the twist angles. For instance, in our systems, due to the presence of the alkyl chain on the central ring, the tilt angle between the phenyl rings is rather large ($60\text{--}70^\circ$), causing a partial electronic decoupling between the phenyls (reduction of π -orbital delocalization between the aromatic rings). Photoinduced electron transfer reactions in the case of Ru23Os(III) are under investigation at the moment. Other authors have investigated homonuclear compounds containing bipyridine as chelating site and a phenyl as spacer (see complexes **21** and **22** in Figure 8) [113] and chiral dinuclear compounds, **24**, have been reported by Lehn and co-workers [114].

Polyphenylene bridging ligands containing terpyridine (tpy)-type chelating sites and different metal complexes as donor/acceptor units, (**25**, **26**) have been reported and their photophysical properties investigated in great detail [24, 33, 36, 74, 115–117]. Due to the short lifetime of Ru(II) terpyridine complexes at room temperature most of the data on the photoinduced processes for this class of compounds have been obtained at 77 K or at 150 K. Photophysical investigation of the Ru–Os complexes has shown that in such compounds a very efficient energy transfer process takes place from the excited ruthenium unit to the osmium moiety (see Table 3) [24, 33, 74, 114–117]. It is interesting to notice that the insertion in the bridging ligand of a saturated unit such as bicyclooctane (bco) (see Figure 5, complex **10a**) causes a dramatic decrease in the energy transfer rate (see Table 1) [74]. This effect is only partly due to increasing distance and can surely be attributed to the insulating character of the saturated bco group.

When tpy groups in the bridging ligand are substituted by cyclometallating units [115c, 125] (complexes containing the bridging ligand **26**; see Figure 8), the rates of energy transfer in the heterometallic compounds **26c**, **26d**, and **26e** are orders of magnitude slower than in the analogous series of noncyclometallated compounds (see Table 3) [115c]. The reason for such a decrease has been explained on the basis of the localization of the lowest excited state on the peripheral ligands and not on the bridging ligands as reported for the analogous noncyclometallated series. In fact, when the N atom of a terpyridine ligand is substituted by a C[–] the σ -donating ability of that coordinating site is much stronger than that of the normal tpy ligand

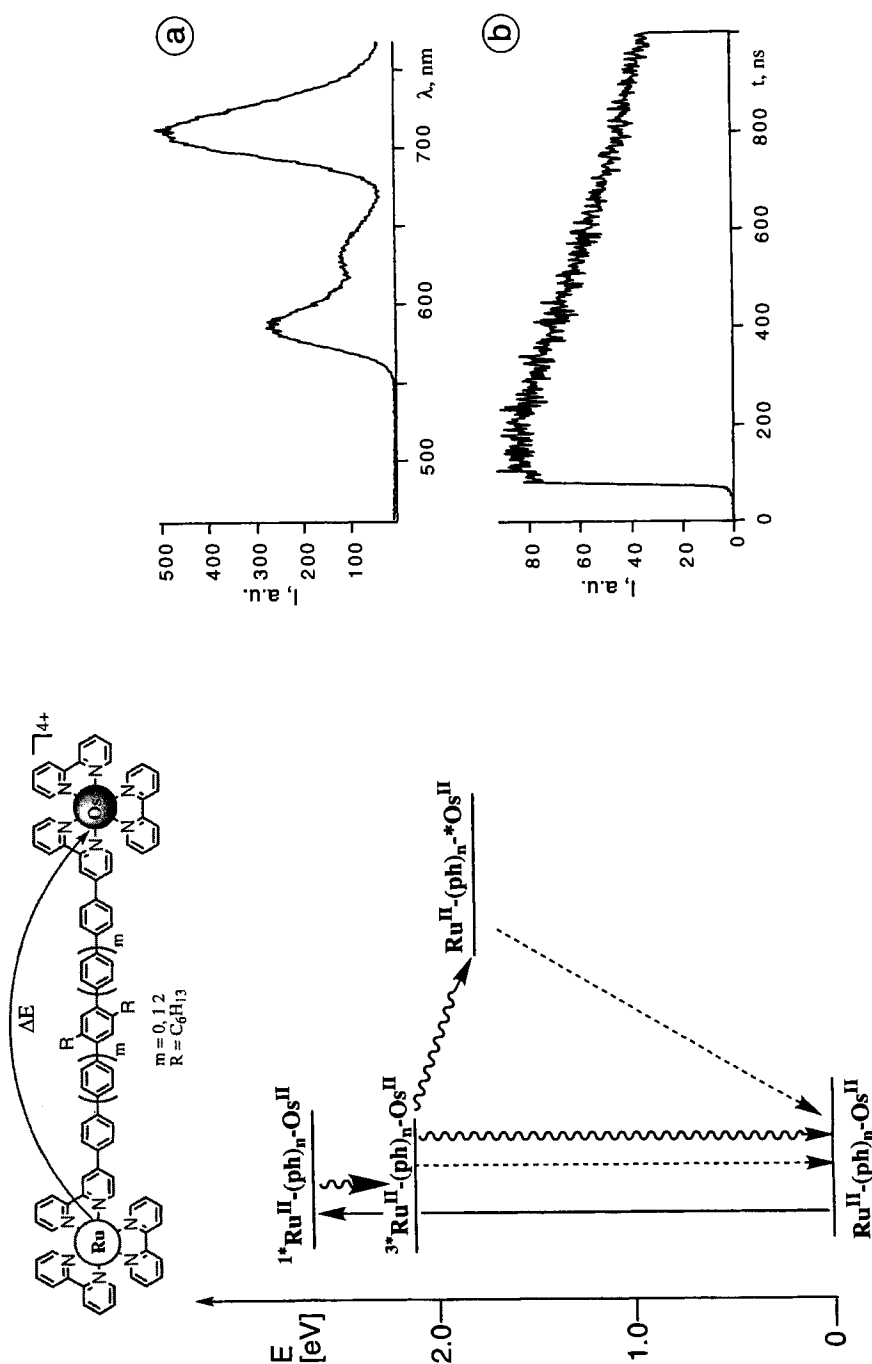

Figure 9. Schematic energy level diagram (left) for Ru23Os compounds. Evidence for the photoinduced energy transfer process can be obtained from a) the emission spectrum (quenching of the ruthenium emission and sensitization of the osmium) and b) the rise time.

Figure 10. Schematic energy levels diagram for the system Ru25Rh.

and therefore a remarkable increase in the electron density in the metal center occurs. As a consequence the first reduction and the lowest-lying MLCT states are centered on the terminal ttpy ligands. According to the above discussion the energy transfer process will occur over a distance greater than that of the analogous non-cyclometallated series. An attenuation factor, β , of 0.33 \AA^{-1} has been reported [74].

Scandola et al. have investigated the behavior of heterometallic dyads Ru(II)–Rh(III), **25e–25g**, at room temperature and at low temperature to elucidate the mechanism for photoinduced electron transfer processes [117]. In such systems the energy level diagram schematized in Figure 10 clearly shows that electron transfer can occur upon excitation of one of the metal-based components. However, due to the low exergonicity of the electron transfer process, no evidence for photoinduced electron transfer in compounds **25e–25g** was obtained at low temperature [117a]. At room temperature, however, some data were reported suggesting a quite efficient electron transfer able to compete with the short-lived excited state of the ruthenium moiety, see Table 3 [117b].

3.6.4 Other Conjugated Systems

A special class of conjugated systems are those containing triple bonds and aromatic units as part of the bridging ligand and schematically represented by the

Figure 11. Dinuclear complexes containing aromatic units and oligoynes as bridging ligands.

compounds **27–32** [70, 72c, 100] reported in Figure 11. The compounds **30** and **31** [70] exhibit different rates for photoinduced energy transfer processes, due to the variation of the triplet state energy localized on the connector (phenylene or naphthalene). Assuming a superexchange mechanism for the energy transfer process, the energy gap between the donor and the lowest excited state of the bridging ligand becomes an important factor for the rate of the photoinduced process. The rates observed for such compounds (see Table 4) are in agreement with the observation that the triplet energy of the naphthalene-based connector is much lower than that of the phenylene-bridged system, therefore favoring the energy transfer process. More complicated is the situation for complexes **28** and **29** since in the latter case

^a abbreviations are defined in the text, ^bRu → na, Ru → an and Os → na denote rate constants for the processes involving the ruthenium or osmium moiety and the anthracene (an) or naphthalene (na) contained in the bridging ligand (for more details see text), ^cna → Os is the rate constant for the process involving the naphthalene contained in the bridging ligand and the osmium moiety.

Figure 12. Other dinuclear complexes containing conjugated bridging ligands.

energy transfer proceeds by intermediate population of the triplet localized on the bridging ligand. In such a situation forward and back processes can occur (see Table 4).

Schanze and co-workers have reported several studies on oligomers and polymers containing Re and Ru units in the ligand **32** [126, 127].

Among other dinuclear compounds (see Figure 12) containing rigid bridging ligands, **33–37** [68, 128–130], those based on tpphz (tetrapyrido[3, 2-*a*:2',3'-*c*:3'',2''-

h:2'''-3'''-*j*]phenazine, **35**, are particularly interesting for their aromatic character, planarity, and lack of flexibility [68]. In the complex **35c** a very efficient energy transfer process has been observed (see Table 5) [68]. The energy transfer mechanism was assigned in a first approximation as a Dexter-type process. However, the authors pointed out that for such a bridging ligand the excited electron remains in a common localized LUMO positioned on the bridging ligand and it is therefore more appropriate to discuss the process of interconversion between the lowest excited states as an electron transfer process [68].

Hong and co-workers have investigated the photophysical behavior of complexes **36a** and **36b** containing cumulene systems as bridging ligands [128]. It is interesting to note that even though the structure is similar to acetylenyl chains the electronic properties are very different and depend on the number of carbon atoms. Whereas acetylenyl ligands are conjugated, in the cumulenic chains each additional carbon will cause the terminal groups to be rotated 90° relative to each other. Therefore the two metal units will be perpendicular in the system when the bridging ligand contains three carbons (C₃) (**36a1**–**36a3**) whereas the C₄ bridge will arrange the two terminal metal complexes in a coplanar structure (**36b1**–**36b3**). The electronic interaction and therefore the rates of energy and electron transfer processes will therefore be strongly influenced by the difference in electronic communication due to the different structures in chains of different lengths. Such observation has been recently confirmed and the energy transfer process for the compounds **36b3** resulted indeed faster [128a] than for the analogous shorter dinuclear complex **36a3** [128b] (see Table 5). The authors suggested a Dexter-type mechanism for the photo-induced triplet energy transfer processes.

In the systems **37** reported by Constable et al., 2,5-thiophenediyl spacers have been used for the assembly of ruthenium units [129]. Photoinduced processes have not been published yet to clarify the role of the thiophenediyl as linker.

3.7 Modulation of the Electronic Interactions in Dinuclear Complexes

The rate of photoinduced processes can be tuned by changing the solvent or temperature, but more interestingly by changing the geometry and/or electronic properties of the bridging ligand. In principle there are several approaches to achieve the change in conductivity and therefore to gate electron transfer reactions. Among the most interesting ways to tune the electronic interactions between the donor and acceptor moieties, those that can induce a reversible modification, by an external stimulus, of the geometric and/or electronic properties of the bridging ligand are the most appealing. The changes in geometry of the bridging ligand that are due to planarization of a conjugated bridging ligand or to coordination of a cation or anion in suitable sites of the bridging ligand have been the most investigated [4, 100, 131, 132].

All of the conjugated systems that have been reported in the past few years [2, 4, 22, 23] exhibit a more or less rapid saturation of the effective conjugation length

(ECL) and hence of the HOMO–LUMO gap for chain lengths noticeably shorter than the maximum dimension [4, 133, 134]. Since this saturation originates from π -electron confinement related to structural factors such as rotational disorder or resonance stabilization energy, oligomeric structures with a more planar geometry should in principle exhibit improved π -electron delocalization. Planarization is not the only way to improve the electronic conduction of the bridge, however, and in some cases the elongation of the bridging ligand, increasing the number of spacers, can play an important role [66]. The possibility of modulating the rate of a photoinduced process or reaching a quasi-wire behavior relies on the mechanism of transfer. In many cases the long-range electron/energy transfer reactions in metal complexes occur via a superexchange-type mechanism due to the large gap between the HOMO orbital of the donor and the LUMO orbital of the bridging ligand (see Figure 13, case a).

When the molecular orbital energy levels of the bridge are very close in energy (nearly resonant) to the levels of the donor, the superexchange is no longer the mechanism responsible for the charge transport. Electron hopping becomes the main mechanism and in principle the rate of the photoinduced processes becomes independent of the length of the bridging ligand, which behaves as a real molecular wire (Figure 13, case b). If the lowest excited state of the bridging ligand lies below the lowest excited state of the acceptor unit the occurrence of photoinduced processes between the components is precluded (Figure 13, case c). Therefore, a careful

Figure 13. Schematic representation of the energy levels of a dinuclear system and tuning of the rate for a photoinduced process changing the excited-state properties of the bridging ligand, BL (for more details see text).

design for a multicomponent system could lead to molecular wire behavior for systems of a certain length. The increase in the number of monomer units in a π -conjugated oligomer causes a decrease in the energy of the triplet excited state due to an increased delocalization length until the convergent limit (ECL) is reached [133, 134]. Taking advantage of this decrease in the triplet state energy of the π -conjugated spacer, one could switch the energy or electron transfer mechanism from superexchange-mediated to exoergonic hopping, Figure 13, with a dramatic increase in the rate of the process, similar to that described for photoinduced electron transfer in the organic system reported by Wasielewski [66]. In such a case one could observe a decrease in the rate of photoinduced processes for a certain number of units and then a sudden increase for longer systems.

It should be pointed out, however, that the modification of the electronic properties of the bridging ligand often has profound influence on the photophysical and electrochemical behavior of the donor and acceptor moieties. Furthermore, the energetic situation depicted in Figure 13, case b, could lead to complete delocalization of the electronic energy or charge and control of the excitation site could be prevented. Therefore the insertion of an “insulating” unit between the donor and the bridging ligand could prevent this undesirable situation.

To our knowledge no examples of inorganic systems showing a wire-type behavior with increasing length of the bridging ligand have been reported.

Some examples have been reported where, upon coordination of an anion [131] or cation [110, 132] or methylation [100] of a unit inserted in the bridging ligand, it is possible to modify the electronic interaction between the terminal units (see Scheme 2).

In particular, concerning the photoinduced processes it has been shown that in the heterometallic system **40** (Scheme 2c) the energy transfer process (Dexter-type mechanism) is slowed down 3000-fold by insertion of a Pt(II) center into the butadiynyl bridge ($k = 1.3 \times 10^7 \text{ s}^{-1}$) [67c, 111]. The authors explained this behavior by the change in the HOMO–LUMO energy gap between donor and bridging ligand, induced by coordination of the Pt moiety that raised the energy of the ethynyl units. As a consequence, a lower magnitude of electronic coupling and therefore a slower rate for the photoinduced processes is expected. Furthermore, the authors suggest that coulombic energy transfer could play an important role in the Ru–Pt–Os system [110].

A similar behavior has been reported by Beer et al. [131] for the complex **38** (see Scheme 2a) for which upon coordination of chloride anions the rate constant of the energy transfer process decreases, indicating a weaker electronic interaction between the excited Ru-based unit and the (Os-based) acceptor component.

Another example of modulation of the electronic interaction between two metal units is schematically represented by compound **41** in Scheme 2(d), for which upon complexation of the vacant 2,2'-bipyridine a perturbation of the luminescence properties of the ruthenium moiety was reported [100]. Methylation caused a quenching of the emission, most likely due to photoinduced electron transfer from the terminal chromophores to the central viologen-type unit.

Finally the possibility to switch photochemically or electrochemically the electronic nature of the bridging ligand to build up tunable systems is still the dream of

Scheme 2. Modulation of the electronic interactions in dinuclear complexes upon coordination of a) an anion; b) and c) a cation; or d) methylation of a central unit (for more details see text).

many researchers. Recently Lehn and co-workers have reported metal complexes connected to a photochromic system, a dithienylethylene derived from a perfluorocyclopentene, **42** (Scheme 3a), in which the electronic interaction could be controlled by the state of the bridging ligand (see Scheme 3) [135]. Upon light excitation interconversion of the bridging ligand between a nonconjugated ("open form", colorless) isomer to a conjugated ("closed form", deeply colored) one occurs [135]. At the moment no data have been reported for photoinduced processes in homo- or heterometallic systems.

We have reported a three-component **Ru–An–Os** species, complex **43a1** (see Scheme 3b), in which an efficient energy transfer from the ruthenium unit to the Os-based component occurs in deaerated solution [136, 137]. The rate constant for the process was found to be $4.7 \times 10^8 \text{ s}^{-1}$ [136]. The occurrence of energy transfer from

Scheme 3. Examples of photoactive bridging ligands.

Figure 14. Schematic formulas and energy level diagram of a species where energy transfer occurs (left) and can be switched off (right).

the Ru-based to the Os-based component of **Ru–An–Os** can be explained on the basis of the relative energy positions of the ^3CT levels of the two metal-containing units (Figure 14a). The structure of the supramolecular species and the energy level diagram suggest that the lowest triplet excited state of anthracene (T_1) is directly involved in the photoinduced process. In air-equilibrated solutions, continuous irradiation causes a photoreaction, formation of singlet oxygen, followed by attack of singlet oxygen on an anthracene ring to form an endoperoxide derivative. As a consequence of this photooxidation the delocalization on the bridge is reduced and the T_1 excited state moves to much higher energy. The lack of a suitable energy level in the bridge precludes the occurrence of energy transfer from the Ru-based to the Os-based component (Figure 14b) [136].

An interesting example of a redox-responsive bridging ligand, **44**, Scheme 4, has been reported by Otsuki et al [138]. They have investigated the behavior of homo- and heterometallic dinuclear compounds containing a 4,4'-azo-(2,2'-bipyridine) ligand as bridging unit. They observed that in the **Ru44aOs** compound the emission of the luminescent units is quenched because of the low-lying excited state localized on the azo group. No energy transfer can be observed with the neutral bridging ligand that acts as an energy trap. Reduction of the azo group, **44b**, causes a rise in the energy of the lowest excited state of the bridging ligand. As a result an efficient energy transfer from the ruthenium component to the osmium center in **Ru44bOs** is observed ($k_{\text{en}} = 6.3 \times 10^8 \text{ s}^{-1}$) [138]. In system **45** a similar concept is applied since the spacer inserted in the bridging ligand is a quinone derivative [139]. However, the system is more flexible and no rate constants for photoinduced processes have been reported. An interesting potential redox-active bridging ligand, Scheme 4(c), is the polyaniline derivative, but such a system has not yet been investigated for this purpose.

3.8 Conclusions

New synthetic routes make available every day many rigid, long, and tunable systems able to transport charge over a long distance, which could ultimately be used as components for nanoscale electro-optical devices. By comparison of the species containing saturated bridging ligands with those containing conjugated systems, it is clear that the rates of the photoinduced processes are strongly influenced by the electronic nature of the bridging ligands used to build up such dinuclear compounds. We have tried to define some fundamental requirements for a wire-type behavior and to summarize some of the recent achievements in this field. We believe, however, that a deeper understanding of the intramolecular processes is still needed, and we are still far from being able to control and modulate by reversible changes the rates of photoinduced processes.

4 Rectifiers

Alan C. Brady and J. Roy Sambles

4.1 Introduction

In 1959 the eminent physicist Richard Feynman gave a talk to the American Physical Society [1] which is widely regarded as one of the most influential early heralds of nanotechnology. He suggested that the future lay in miniaturization—that it should be possible to manufacture machines and electronic devices from components made of only a handful of atoms. He foresaw that computers could become very useful tools if they were smaller and more complex, by being reduced from room-sized to a size where “the wires should be 10 or 100 atoms in diameter, and the circuits should be a few thousand ångströms across”.

The rapid progress of microelectronics in the guise of semiconductor integrated-circuit technology has followed this trend of miniaturization. Indeed, since the early 1970s Moore’s law—that the number of transistors on a chip will double every 18 months—has been followed. The present cutting-edge devices are fabricated lithographically with a track width of 0.18 µm, while in research systems widths down to 70 nm have been demonstrated. Until very recently it was believed that current MOSFET technology could not function below about 30 nm due to Zener breakdown of the source/substrate junction and current leakage through the gate oxide layer [2]. Even this limit seems to have been bettered; a 20 nm MOSFET transistor has been demonstrated by a group from the CEA at Geneva, and devices such as the dual-gate MOSFET and the vertical-gate transistor are predicted to scale to 5 nm. Building devices which are this small require elaborate electron or ion beam lithography to carve structures which are just a handful of atoms across, and which must not contain any defects. At this scale it would be useful to be able to assemble the materials atom by atom, or molecule by molecule. Organic molecules can be fine-tuned to produce very specific properties, and could be used as the building blocks of nanometer-scale “molecular electronics”. In this section we shall consider the fundamental unit of a molecular-scale logic device, the molecular rectifier.

Figure 1. a) A σ -bridged aliphatic chain; b) a π -bridged molecular wire; c) a σ -bridged molecular wire.

4.2 Molecular Conduction

The principal mechanism for molecular conduction is electron transport through part-filled or empty molecular states [3]. The primary candidates for mediating conduction in organic molecules are perhaps π -bonds, as they have a relatively low excitation energy (the π - π^* gap is typically 1.5–3 eV) and can overlap with neighbouring π -bonds or lone-pair orbitals. This overlap can produce an extended conjugated wavefunction which can facilitate electron transfer over several nanometers. However, the degree of delocalization between two π -bridged moieties, and hence the π - π^* gap width, are highly dependent on the orbital overlap in the plane of the bond. If a torsion is applied to the bond, for example by geometric constraints, the degree of conjugation between the π -orbitals at each end of the bond will fall off rapidly as the twist angle increases [4]. There are no such distortions in the simple polyalkene shown in Figure 1(a), an example of the simplest type of extended molecular conductor or molecular wire. Molecular wires are discussed in detail in other chapters in this section; it is enough for us to know that the ideal molecular wire is a material which has a π - π^* gap which is small enough to allow ballistic transport through the extended system [5].

In contrast, long-chain aliphatic molecules such as the one illustrated in Figure 1(b) are excellent insulators and conduction through such materials occurs by tunneling. This is because saturated bonds (σ -bonds) are very localized along the axis of the bonded atomic centres, and the corresponding antibonding states have relatively high energies in molecular terms (i.e., the σ - σ^* gap is typically of the order of 8 eV for C–C bonds). However, σ -bonds can be used to spatially separate π -bonded regions such as the two ends of the molecule illustrated in Figure 1(c), whilst still allowing electron transfer between them. This is because, whereas “through-space” tunneling becomes vanishingly small beyond the length of two σ -bonds [6], “through-bond” interactions between lone-pair orbitals or isolated π -bonds can be mediated through one or several σ -bonds, although the electron transfer (ET) probability decreases exponentially with the length of the bridge. Marcus ET theory [7] (also see Figure 2) suggests that such transfer can occur rapidly; this has been borne out in spectroscopic studies.

Figure 2. Marcus electron transfer plot for the process $\text{DBA} \rightarrow \text{D}^+\text{BA}^-$ [7]. The electronic coupling between the two states is defined as the energy difference Δ at the avoided crossing. Δ decreases exponentially with bridge length.

4.3 Molecular Rectifier

In the early 1970s researchers at IBM explored the possibility of exploiting the properties described above by using organic molecules as electronic components. In 1974 Aviram and Ratner, working at New York University with support from IBM, proposed that a suitably engineered molecule could act as a rectifier, exhibiting a diode-like electrical response when placed between two metallic electrodes [8]. Their deceptively simple idea is illustrated in Figure 3. The molecule would consist of three parts: an electron donor, an electron acceptor and a rigid “bridge” which would serve to keep the donor and acceptor spatially and electronically distinct. The electronic asymmetry of the molecule would allow electron transfer between the molecule and an external circuit to occur at low applied bias in one direction, and to be hindered in the opposite bias sense.

This mechanism is illustrated in more detail in Figure 4. The junction is simplified so that we consider only the highest occupied (HO) and lowest unoccupied (LU) energy levels of the donor, bridge, and acceptor regions of the molecule and the highest of the electronic states of the metal electrodes. Note that even with no

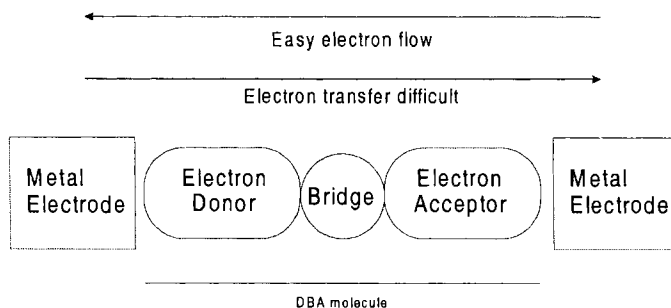

Figure 3. Schematic of a donor-bridge-acceptor molecular rectifier.

Figure 4. The energy levels of an Aviram and Ratner molecular rectifier [8]. a) Zero applied field, ground state configuration; b) forward bias; c) reverse bias (note that $V_{\text{reverse}} > V_{\text{forward}}$); d) reverse bias, alternative mechanism.

applied electric field (Figure 4a) the interaction between these electronic states and the adjacent molecular orbitals will lead to a broadening of the molecular states, and the Fermi edges of the metal electrodes will shift to lie at the centre of local HO–LU gap. Consequently the position of the Fermi edges of the two electrodes will not be symmetric unless the molecule has a symmetric charge distribution at its extremities.

An external voltage applied across the electrodes will induce a potential gradient and hence realign the energy level diagram. In Figure 4(b) there has been an energy shift such that an electron can transfer from the right-hand electrode into the vacant LU level of the acceptor, and an electron from the HO donor level can transfer into the left-hand electrode. Rapid internal recombination will now restore the $D^+\sigma A^-$ molecule to the $D\sigma A$ ground state. This bias sense, which results in “easy” electron transfer, is referred to as the forward bias direction. Figure 4(c) shows how a much larger reverse bias is required for electron transfer to occur in the opposite direction. Electron transport across the molecule is asymmetric with respect to applied bias, and hence the molecule acts as a rectifier. However, there is a further mechanism, shown in Figure 4(d), which can occur under reverse bias. If the energy gap between the HO donor state and the LU acceptor state is small, internal electron transfer can occur. This will be a rapid process, analogous to carrier excitation in a semiconductor, and the right coupling conditions between the donor and the acceptor could result in significant current flow.

Aviram and Ratner carried out a series of calculations using a semi-empirical INDO/CNDO technique to compare the electronic structure and electrical response of a hemiquinone (shown in Figure 5) and a hypothetical candidate molecular rectifier molecule [9]. They chose analogues of tetrathiofulvalene (TTF), a strong donor with an ionization potential of 6.83 eV, and tetracyanoquinodimethane (TCNQ), a strong acceptor with an electron affinity of 2.8 eV, separated by a rigid, cage-like aliphatic bridge to construct the rectifier shown in Figure 6. The calculated electrical response of this material showed a clear rectifying step.

It is reasonable to assume that any molecule that has an asymmetry in its electronic structure, such as carbon monoxide, is potentially a molecular rectifier. An Aviram and Ratner rectifier is merely an extension of this principle in that it is a modular assembly of parts which are well understood from charge transfer studies. The electronic asymmetry of the rectifier is obtained by placing an electron donor at one end of the molecule and an electron acceptor at the other. Some common

examples of organic donors and acceptors are illustrated in Figures 7 and 8. C_{60} (Figure 9) also acts as an acceptor in its native state, and as its chemistry is unlocked it is likely to become an important addition to the molecular electronics tool kit.

The third and perhaps the most important component of the Aviram and Ratner rectifier is the bridge. The purpose of the bridge is to electronically separate the donor and acceptor and to create a ground-state electronic structure that has the HOMO and LUMO localized on different parts of the molecule. It has already been mentioned that σ -bonded bridges can mediate electron transfer between π -orbitals, and indeed the majority of molecules synthesized as molecular rectifiers have used σ -bridges. However, the large σ - σ^* gap means that such systems are limited by an exponential loss of transfer probability with bridge length. Furthermore, the flexi-

Figure 9. Buckminsterfullerene, C_{60} .

Figure 10. $C_{16}H_{33}^+Q3CNQ$.

bility of the bridge resulting from the freedom of rotation about the σ -bonds means that it is difficult to ensure effective donor–acceptor separation.

It is also possible to keep the molecular orbitals of the donor and acceptor separate by ensuring that they are not coplanar, exploiting the fall-off of π -coupling with twist angle described earlier. $C_{16}H_{33}^+Q3CNQ$ (Figure 10) has such a twisted chromophore, arising from steric hindrance, which stabilizes the ground state of the molecule in a charge-separated zwitterionic form. This effect has been further utilized by Ashwell and co-workers in an attempt to produce a material for Second Harmonic Generation (SHG) which does not have a charge transfer absorption band near the SHG emission band [10]. The modified bridge of the dye in Figure 11 effectively splits the chromophore in two, despite the fact that it is π -bridged. Such a molecule may also be a candidate molecular rectifier.

One cannot discuss the manufacture of molecular rectifiers without mentioning the huge volume of work, both in terms of papers published and molecules synthesized, undertaken by Robert Metzger and Charles Panetta [11]. They have refined the complicated techniques required for the synthesis of these materials and produced a large catalogue of potential rectifiers, a selection of which is shown in Figures 12–15. The molecule shown in Figure 12 is very close to the archetypal Aviram and Ratner rectifier. However, a pure sample has never been isolated. The molecules represented in Figures 13, 14, and 15 have been selected to give examples of molecules with different donor and acceptor combinations. In addition, all three

have aliphatic tails for Langmuir–Blodgett assembly (see below). The molecule in Figure 15 is also unusual because it has a nonplanar acceptor.

There already exist a large number of materials in general use or synthesized for other purposes that possess many if not all of the properties of a molecular rectifier. Many liquid crystal materials are designed with a weak donor–acceptor structure in order to give the molecules a large dipole moment (Figure 16 shows a typical cyano–biphenyl nematic material), but as a side effect some of these may have potential as molecular electronic devices. Donor–bridge–acceptor molecules such as the “antenna” material shown in Figure 17 have been synthesized in an attempt to artificially replicate photosynthesis, i.e., to use light to drive chemical reactions.

Figure 16. A typical cyano-biphenyl nematic liquid crystal molecule.

Figure 17. A donor-bridge-acceptor antenna molecule.

These materials are effectively molecular photodiodes. It is highly possible that future applications of molecular electronic devices will arise through this overlap of technologies.

4.4 Practical Investigation of a Molecular Rectifier

We have described how a molecule which has an internal electronic asymmetry should exhibit rectifying properties. However, since we are interested in current flow rather than simply charge separation within the molecule, we must characterize the molecule as part of a circuit. It is important to realize that the measurements being made are of the junction as a whole rather than just the molecular properties. That is to say, the electrical response is a convolution of the molecular properties, the external circuit and, in particular, the contacts between the molecule and the electrodes. The interactions at the interfaces are responsible for many of the effects that are observed in metal-insulator-metal devices.

Aviram and Ratner envisaged that their hypothesis could be tested by sandwiching a monolayer of the rectifier molecules between metallic electrodes, i.e., measuring a two-dimensional (2D) assembly of identically oriented molecules rather than a single molecule. The monolayer would be assembled using the Langmuir-Blodgett (LB) technique, which at the time was the only reliable means of constructing an ordered molecular monolayer. There are a number of more recently developed techniques which could clearly now also be used. The major candidate is self-assembly, which utilizes the propensity of thiols to chemisorb onto noble metal surfaces, and

Figure 18. Possible orientations of π -orbitals with respect to the electronic surface states of the electrodes. The normal LB geometry would be the right hand case.

has major possibilities for device fabrication. However, the sulphur–metal bond can in itself act as a tunnel barrier and exhibit rectifying effects.

Even within a monolayer there is the possibility of in-plane intermolecular interaction [12]. Adjacent π -systems can interact to form a 2D band or a pseudo-1D band structure within the layer, resulting in dispersion of the individual molecular orbital levels. It should be possible to isolate single-molecule effects by diluting the rectifier material in an inert matrix, e.g., a fatty acid. The current should then scale with the area fraction of active molecules within the matrix, if it is assumed that the rectifying current is the dominant conduction mechanism.

The use of a 2D film of molecules raises a further consideration related to the interface states. The orientation of the molecular π -cloud with respect to the surface states of the metal electrode will very strongly influence the ET probability. In LB films and self-assembled monolayers, the π -orbitals are generally aligned so that they are almost orthogonal to the plane of the metallic substrate. Consequently the overlap with the surface states of the metal is poor, and hence the ET probability between the two is low. Ideally the junction should be arranged so that the molecular states lie in the same plane as the surface states of the metal, as shown in Figure 18. This has not yet been attempted with rectifying molecules; the coupling efficiency has been reliant upon the native layer tilt of the molecules within the LB film.

Langmuir–Blodgett films have been at the heart of the majority of molecular rectifier studies to date. A brief description of the technique follows.

4.5 The Langmuir–Blodgett Technique

An amphiphilic molecule will preferentially sit at an air/water interface with the hydrophilic group immersed in the water and the hydrophobic part clear of the surface. A direct consequence of this is that insoluble amphiphiles will form a monolayer at the interface. With no external constraints this will be disordered, but as the available surface is restricted, the molecules will align and pack into an ordered 2D pseudo-crystalline state (as shown in Figure 19b). This ordered semi-rigid structure

Figure 19. a) Simple representation of an amphiphile; b) Langmuir monolayer in expanded and compressed states; c) vertical and horizontal Langmuir–Blodgett film transfer; d) X-, Y-, and Z-type LB films.

can be transferred onto a solid support by either vertical or horizontal transfer (Figure 19c). Many amphiphilic materials can be built into multilayered structures using repeated monolayer deposition. Three different orientational structures are shown in Figure 19(d).

A drawback of the LB technique for producing electrical samples is its reliance on amphiphiles. Aviram and Ratner suggested that the donor part of their rectifier would be sufficiently hydrophobic for LB deposition. It is more generally found that a long aliphatic tail has to be added to one end of the molecule to make it strongly hydrophobic. This is a tunnel barrier, and can result in the through-space tunnel current being of a similar magnitude to the transmitted current in a monolayer. Furthermore, LB films have inherent defects at grain boundaries such as that illustrated in Figure 20, and these defects tend to be more prevalent in more complex, heavily substituted materials. It is critically important to produce films which are as defect-free as possible in order to make a junction which is not a short circuit. The majority of workers have chosen to study multilayer structures, despite the complication of interpretation arising from multiple interfaces. There will be a potential

Figure 20. Grain-boundary defect in a LB film.

drop at every interface, and as a result it is by no means clear what the electric field will be across each layer (see Figure 21). Furthermore, in order not to have reversed the electrical response of the molecules in every other layer, the structure must be noncentrosymmetric, i.e., X- or Z-type. Even then tunnelling may overshadow the molecular conduction process.

Tunneling in multilayered LB films is defect-mediated via trap sites within the conduction band of the molecules (Poole conduction), or by Schottky emission between widely spaced trap sites (Poole–Frenkel conduction) in thicker samples [13]. With good molecular conductors the current from molecular conduction should dominate the small contribution from tunneling. However, the conduction mechanism between adjacent layers is not always obvious, due to the complexity of the interface structure.

Careful use of the Langmuir–Blodgett technique allows the assembly of an oriented molecular film onto a solid support, which could be one of the electrodes in our electrical circuit. This circuit must now be completed by adding a second metallic contact on top of the film.

4.6 Junction Design

Defects in the film are perhaps the primary cause of short circuits in junctions. The junction design, that is to say the electrode geometry and materials, has to be chosen to minimize defect formation. There are broadly two classes of junction geometry, and these are illustrated in Figure 22. The simplest structure consists of a linear base electrode on an insulating substrate; a linear top electrode is then deposited perpendicular to the base electrode. This strategy can be used to make very small junction areas, minimizing the probability of including a defect while distancing the connection to the external circuit. However, the edges of the base electrode (and the penumbra associated with it if the electrode is thermally evaporated) are in themselves prime sites for defect formation in the LB film. The second geometry eliminates the edge problem by utilizing a planar base electrode and small pads for top electrodes. The problem with this geometry is that making a connection to the top electrode is difficult with most fragile molecules.

In both cases the base electrode should be flat and smooth, and free from any contamination or oxide layers. Ideally both of the electrodes should be noble metals so that there is no possibility of any oxide layers in the junction. However, the majority of LB films are not very thermally stable, and are easily damaged during top electrode deposition. This is a particular problem with noble metals, which

Figure 21. Electric field profile across multiple interfaces: a) across an air gap the potential gradient is uniform; b) with a molecule in the gap, there will be a potential drop which can be different at each interface (note that the potential gradient along the length of the molecule is not necessarily uniform, as illustrated in case 2); c) with a multilayer of molecules, there is an extra interface between each layer.

Figure 22. Classes of electrode geometry: a) crossed-wire electrodes; b) planar base electrode with pad top electrode.

have high evaporation temperatures (1500 °C for gold) and a large latent heat of condensation.

Thus, so far, few measurements have been conducted on the ideal gold|LB|gold system—instead, other top electrodes are used which inflict less thermal damage on the LB film. The measurements that have been made are outlined below.

4.7 Electrical Characterizations of LB Films

The first measurements of the electrical properties of LB films appear to have been carried out by Buchwald et al. in the 1930s using an electrolyte in place of a second electrode [14]. It was not until the 1960s the first metal|LB|metal experiments were undertaken by Handy and Scala [15] and were followed by a major contribution by Mann and Kuhn which included the first Al|LB|Al experiment [16]. Aluminum has an insulating native oxide which strongly influences the results of characterizations carried out using it as an electrode [17]. Only in the late 1980's was the first electrical characterization of LB films without oxide layers on the electrodes carried out by Geddes et al. [18], in the first study to emphasize the critical importance of producing defect-free LB films for junction fabrication. They used a junction geometry with a planar platinum base electrode and magnesium top electrodes which were capped with silver contacts, similar to the geometry shown in Figure 23 (which actually shows a later refinement of this original innovative solution). Connection was made using droplets of gallium/indium eutectic to bridge between the silver pads and a gold wire. Geddes also reported seeing the asymmetric I/V response shown in Figure 24 from LB films of DDOP-C-TCNQ (Figure 25), although the molecular origin of the effect was never fully explained [19].

Rectification in a monolayer and multilayers of $C_{16}H_{33}\gamma Q3CNQ$ (Figure 10) was observed by Martin and co-workers [20]. Typical data from a multilayer sample are shown in Figure 26. The rectification was convincingly shown to be molecular in

Figure 23. Junction geometry used by Geddes et al., Martin and co-workers, and Brady et al. [19, 20, 23].

Figure 24. I/V characteristics of a monolayer of DDOP-C-TCNQ [19].

origin by insulating the active molecule from the electrodes with inert layers [21]. These measurements have recently been repeated and confirmed by Metzger et al., who have carried out a large number of corroborative spectroscopic studies [22]. Unfortunately this group has taken the retrograde step of moving back to aluminum electrodes in an attempt to produce “symmetric” junctions. There will always

Figure 25. DDOP-C-TCNQ.

Figure 26. I/V characteristics of a five-layer film of $C_{16}H_{33}/Q3CNQ$ [20].

be a large element of uncertainty in the interpretation of any measurements obtained from a junction containing oxide barriers.

A σ -bridged material, OHAPy-C-DNB (Figure 27) has been studied by Brady et al. [23]. This material exhibits very strong rectifying effects (Figure 28), but the direction of high current flow does not fit the simple Aviram and Ratner model. Instead, it is believed that this material acts more like an organic semiconductor, in a manner similar to the “alternative” reverse-bias mechanism shown in Figure 2(d).

Figure 27. OHAPy-C-DNB.

Figure 28. I/V characteristics of a five-layer film of OHAPy-C-DNB [23].

Figure 29. Behavior of computationally modeled HOMO–LUMO gap under applied electric field [23].

Ab-initio modeling indicates that the HOMO–LUMO gap changes in width in the high electric fields involved in these experiments, as shown in Figure 29, and this probably dominates the rectification behavior. Furthermore, it is believed that the distortion of the molecular orbitals in the huge electric fields is responsible for the nonlinear conduction observed.

The crucial step of manufacturing gold|LB|gold junctions which can be cooled to 4.2 K has been achieved by a group from Stuttgart [24]. They have observed rectification from multilayer heterostructures, and recorded what are believed to be

the signatures of molecular orbitals filling and emptying. The materials they have studied to date have been thermally robust phthalocyanines and porphyrins, but the importance of the technological step cannot be understated.

4.8 Other Techniques

Other technologies are also emerging which allow single molecules to be addressed. Scanning probe microscopy allows a conducting tip to be placed on a partial or complete monolayer with atomic precision. A number of materials, including benzene and C₆₀, have been probed with a scanning tunneling microscope (STM) [25]. Nanoelectrodes are being fabricated with gaps down to 10 nm [26], and a single dithiol molecule has been trapped in a break junction [27]. These studies herald the arrival of truly molecular electronics.

4.9 Conclusions

Unimolecular rectifiers are a reality. They have been made and they have been measured. However, there is still substantial room for improvement in the experimental techniques used to study the molecules and in the molecules used to give improved thermal stability. Current experiments need to be modified so that noble metal electrodes may be used to study a dilute monolayer, ideally at low temperature where molecular orbital signatures will be observable. This already has been achieved with “robust” molecules such as phthalocyanines, which suggests that the technological step to be made is not too great.

At the moment molecular electronic circuits and logic devices are still some distance away, but the building blocks are there and the tools are being assembled.

5 Logic Gates

A. Prasanna de Silva, Nathan D. McClenaghan, and Colin P. McCoy

5.1 Introduction

It is hard to ignore the influence the information technology revolution has had on the practice of chemistry. Then it is only fair that we as practitioners of chemistry apply our particular skills to examining some of the principal revolutionaries—the logic gates [1, 2]. If nothing else, such efforts will infuse the computational ways of thinking into our culture, and besides causing such cross-fertilization, they can access niche applications of single molecules (or small populations of them) with logic capabilities. Applying chemical or optical inputs and receiving optical output from molecules according to various logic types is no longer a dream. Therefore sensory applications of these molecular-scale logic gates are to be expected, especially for use in small spaces. Other approaches to information processing with molecules or atoms have also come to the fore. The spectral hole-burning approach has already led to parallel arithmetic operations. The huge parallelism inherent in DNA-based computation has been demonstrated. The possibilities of quantum computing in several of its manifestations have excited interest. When compared with current semiconductor devices, the far smaller size of molecules and atoms remains an important feature to exploit in this and other ways.

Other features of current molecular logic systems, such as the rudimentary logic capability, the solution-phase operation, and the difficulty of physical “wiring” of simpler systems into more complex ones, are viewed as fatal disadvantages by those bent on channeling current research slavishly along the beaten track of silicon technology. These issues can be debated. When we view them more generally, we realize that the logic capabilities are being steadily generalized and developed in spite of the relatively meager resources invested thus far, i.e., with a rather high benefit/cost ratio. We also notice that wet operation of molecule-based information processors has served humankind well ever since its beginning [3]. Furthermore, molecular logic systems can be transplanted to surfaces when so desired. The physical “wiring” problem has been circumvented, at least in some prototype cases.

Designers of molecular logic gates have the prerogative to be educated by silicon technology and yet not be bound by its attitudes and culture, all-pervasive though it may be. This debate aside, one general way of addressing this challenge will be to look for applications where these issues are not involved.

The area of molecular logic and information processing, like any embryonic field, faces several common issues. On the one hand, in order to grow it needs new exponents. On the other hand, these new exponents may occasionally make over-enthusiastic extrapolations leading to criticism by the chemical community. We must carefully consider cautionary remarks, expressed most recently by Bard [4], if this field is to prosper.

Even though molecular electronics [5, 6] has been a sphere of scientific effort since the 1980s, it is only since 1993 that molecular-scale logic gates have become available in the primary literature [7]. Coincidentally, some of the experimental tools required to examine these gates at the single-molecule limit became available [8, 9]. These examinations should be a priority for the future. As the following sections will demonstrate, molecular-scale logic gates arrived rather suddenly without going through intermediary stages. In contrast, molecular-scale electronic logic gates have not yet been realized, although steady progress is being made with the development of wires [10], switches [11], and diodes [12]. On the other hand, the current generation of molecular-scale logic gates are being generalized as we write. Logic functions of various types have been arranged within single molecules. These cover over half of the nontrivial cases out of the four single-input and the sixteen two-input logic families [13]. The emphasis in this chapter will be on tracking the progress of these ideas and related developments in other approaches to atomic/molecular-scale information processing. We provide this status report for all interested scientists to ponder and build on. As this is a naturally interdisciplinary subject, everything here is offered as a series of thumbnail sketches from a chemist's perspective. For deeper analysis, the reader is encouraged to consult the original references.

5.2 Photochemical Approaches to Molecular-scale Logic

5.2.1 Chemical/Optical Input/Output

Combination of ideas from organic, coordination, supramolecular, and photochemistry provides a simple approach to logic operations at the molecular scale. It is straightforward to marshal inputs, outputs, and power supplies if they are all distinguishable. Truly molecular devices thus arise naturally [14–16]. The subsections below show how this can be done by using a mix of various chemical species and different wavelengths of light. In most cases so far, the optical output is considered in the fluorescence mode because of its ease of detection even at the single-molecule limit [17, 18]. Using light absorption (or transmission) as an output is normally a less sensitive approach, though single-molecule experiments are becoming possible even here, albeit under special conditions [19, 20]. If the absorption

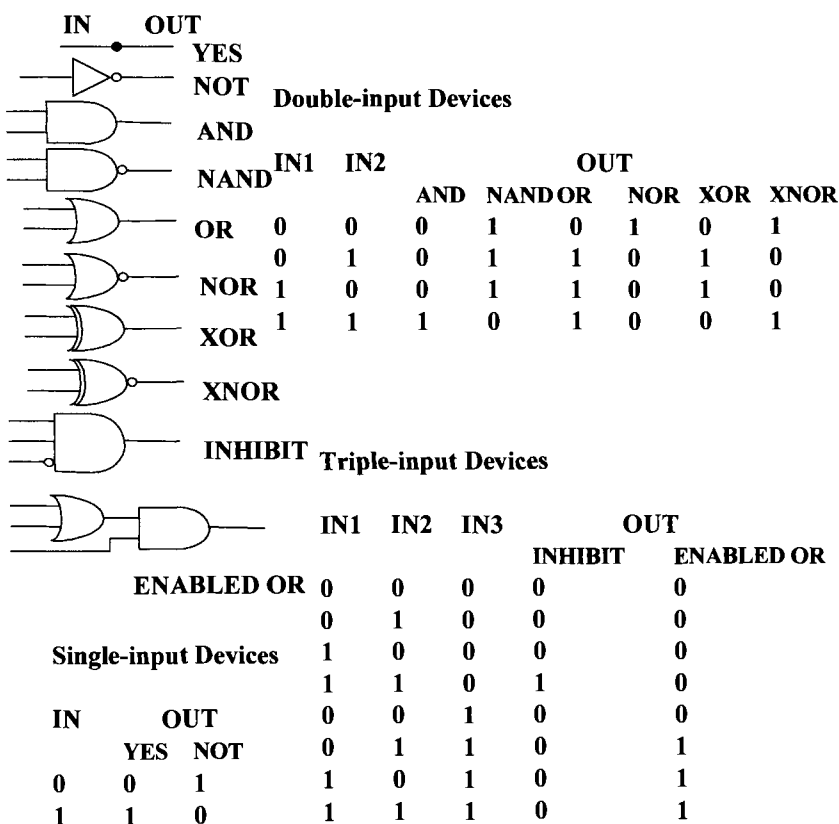

Figure 1. Electronic symbols for logic gates and corresponding truth tables.

mode is considered more seriously, many earlier experiments from the analytical chemistry area [21] also become available for discussion in the present context. In spite of this bounty the discussion is limited to an example or two of each type, owing to space constraints and also to maintain balance between the different sections. More detailed discussion on the photochemical approach is available in two companion reviews [22, 23].

YES logic

A YES logic gate is the simplest of all gates, with a single input channel and a single output channel. A low input (input 0) gives a low output (output 0) (Figure 1). Conversely, a high input (input 1) results in a high output (output 1).

There are literally hundreds of examples of this type of behavior, most of which have been developed for other applications by their original authors and are therefore not recognized in this logical context. Using appropriate codings any bistable system with an easily recognizable physical output would fall into this category. A fluorescent photoionic example can be seen in Figure 2 with 1 [24], whereby protons

Figure 2. Molecule **1** displaying YES logic via fluorescence output from a proton input.

are considered as the input and fluorescence emission intensity at a chosen wavelength within the emission band is the output. In the absence of protons (input 0) an electron can be freely transferred from the amine to the anthryl fluorophore in its excited state, with a resulting quenching effect on the fluorescence emission (output 0). This is photoinduced electron transfer (PET) [25–29]. Introduction of protons of sufficiently high concentration (input 1) causes binding of the amine receptor, which has the effect of ceasing this relatively long-range electron transfer and hence restoring the fluorescence output (output 1), **1b**. Thus **1** can be seen to convert two different kinds of signal (ionic to photonic). Many variations in the input species employed and output measured have been reported. The literature of absorptiometric and fluorescent reagents for protons and metal ions in analytical chemistry is a particularly rich source, provided that adequate care is paid to binding reversibility [21, 30, 31].

NOT logic

Another one-input, one-output gate is a NOT gate. This gate can be considered an inverted YES gate, as can be seen by the electronic representation in Figure 1. The corresponding truth table for this logic situation can also be seen.

In the example seen in Figure 3, a PET process is again implemented. However,

Figure 3. Molecule **2** displaying NOT logic via fluorescence output from a proton input.

in this example the quenching mechanism is set in place only upon protonation. Therefore the input is again protons and the output is fluorescence emission. The deprotonated carboxylic acid group in **2a** [32] exhibits a near-zero Hammett substituent constant, resulting in a small net effect on the adjacent benzene ring. Therefore this substituent has only a small effect on the reduction potential of this entity. However, protonation of the carboxylic acid group results in a much greater electron-withdrawing ability which is conferred upon the adjacent benzene ring, **2b**. The lowered reduction potential of this moiety makes the quenching mechanism favorable. Thus introduction of a high proton concentration (input 1), 10^{-2} M, yields a low fluorescence emission (output 0). At a low proton concentration (input 0), 10^{-6} M, the inefficient PET process results in switching “on” fluorescence (output 1).

Again, it is important to note that there are many examples of NOT logic gates scattered throughout the fluorescence literature, of analytical reagents for metals for instance [31]. This is to be expected since the quenching of fluorescence is a common phenomenon, especially with the transition metal ions.

AND logic

Previous examples considered required a one-input, one-output format. In the AND logic situation and subsequent gates under consideration, a minimum of two inputs are required. This two-input, one-output situation can be seen in Figure 1 along with the resulting truth table.

As two inputs are required, two different ionic species can be considered as the inputs when supplied in sufficiently high concentration. In the case of **3** [33] (Figure 4), Na^+ and protons are employed. The benzo-15-crown-5 ether and tertiary amine nitrogen serve as the respective binding sites. An essentially digital action is seen in this case; in other words, the low-fluorescence cases are characterized by measurable emission being almost absent, due to the efficient PET processes in this molecule. With neither Na^+ nor H^+ present (input 00), **3a**, PET can occur from either receptor with no resulting fluorescence emission (output 0). With only Na^+ (or H^+) present, electron transfer from its receptor is halted (output 0). However, electron transfer from the other receptor can continue unabated and so no fluorescence is detected. This corresponds to the input 10, **3b** (or input 01, **3c**), output 0, situation. With both Na^+ and H^+ present (input 11), the PET mechanism cannot function from either receptor and so fluorescence is switched “on”, giving an output 1, **3d**. The PET process shown in **3c** deserves special comment. A quick look at the relevant electrochemical data would show that PET from a *o*-dialkoxybenzene unit to an anthracene is thermodynamically unfavorable. The intramolecular nature of the current situation does not change this conclusion, as confirmed experimentally with the appropriate model compound [34]. However, the substitution of anthracene in a *meso* position with a strongly electron-withdrawing substituent swings this situation around. Now PET thermodynamics becomes favorable, as seen with 9-cyanoanthracene derivatives, for example [34]. The fact that **3c** contains a protonated aminomethyl substituent in a *meso* position of the anthracene is therefore pivotal to the successful operation of AND gate **3**.

Figure 4. Molecule 3 displaying AND logic via fluorescence output using sodium and proton inputs. Note that only one of the two PET paths shown would occur in a given excited state 3a.

In a preceding case [7], indeed the first example of this behavior, **4** was seen to behave in a similar fashion employing the same inputs and outputs being constructed from similar components. However, the same degree of switching between “on” (output 1) and “off” states (output 0) was not seen. This was attributed to the

Figure 5. AND logic with **5** via fluorescence output with combined ionic (H^+) and photonic inputs (365 nm light).

arrangement of components, with the benzo-15-crown-5 ether receptor three atoms away from the fluorophore.

Pina, Balzani, and their colleagues developed a different approach to molecular-scale AND logic. In the case of **5** [35] (Figure 5), protons and 365 nm light were utilized as the inputs, thereby differing from the all-ion input strategy shown previously. The proton input is considered low at a concentration of 10^{-4} M, and high at 10^{-1} M. This combination of an ionic input followed by photonic one then consummated in the photochemical isomerization seen in Figure 5. Unlike its precursor, the newly formed molecule emitted fluorescence, and thus emission (515 nm) served as the output. Irradiation of **5** caused smooth *E*- to *Z*- isomerization of the alkene to produce **7**, which then allows proton-induced cyclization to **6** via intermediate **8**. These systems are elegant because of their extreme structural simplicity and understandable mechanistic/operational complexity, because of which their importance extends beyond logic operations to include the “write–lock–read–unlock–erase” cycles [36] as well as shallow and deep memories.

We must again draw attention to venerable analytical reagents which show features of AND logic. The importance of pH control is stressed during assays of metal ions, for instance. Therefore, alkaline conditions (proton input 0) produce no signal (output 0) even if the metal ion is present (metal input 1). Upon adjustment of pH to neutral conditions (proton input 1), the presence of metal ion (metal input 1) produces an analytically useful fluorescence/absorption signal (output 1) [31]. Further increase of the proton level is detrimental to many of these cases, resulting in the loss of fluorescence/absorption. Simpler systems, some of which are metal-free, can be predictively designed to show such “window” or “off–on–off” effects [37–40].

Figure 6. NAND logic with **9** via fluorescence output using Ba^{2+} and SCN^- inputs.

NAND logic

In operational terms a NAND operation can be considered as an AND logic gate with a NOT logic function imposed upon its output. The symbols used and the corresponding truth table are shown in Figure 1.

Even though not originally discussed as such [41], **9** was the first case of a well-behaved fluorescent NAND logic gate. The strategy employed in the derivation of this system can be seen in Figure 6, whereby a cation receptor is coupled to multi-heteroatom fluorophore. The action displayed here is noncommutative in the sense that binding of a thiocyanate ion, which is one of the inputs, can only occur if the other input, Ba^{2+} , has previously been bound. The Ba^{2+} is bound at the 15-crown-5 ether site, but as this ion is large in comparison with the crown ether cavity, the possibility exists for cooperation of the ester carbonyl group as a lariat. The large residual charge is counteracted by the binding of an SCN^- to the Ba^{2+} in an apical fashion. This easily oxidizable SCN^- can undergo PET to the excited fluorophore, **9b**, with a resultant quenching action. Thus a photoactive dyad can be seen to be formed, where the receptor is not directly involved in electron transfer. The incorporation of two nitrile groups and an ester group into the fluorophore make the reduction of the fluorophore in the excited state more facile and the resulting PET process is not surprising. The authors discussed this in a logical AND context but it would be more consistent with other systems discussed in these pages if it were interpreted as a NAND gate.

OR logic

Another two-input, one-output gate is the OR gate whose electronic symbol and corresponding truth table can be seen in Figure 1. The output can be seen to be high in the presence of one or two high inputs. The output is low only when no high input is present. It should be noted that the number of input channels could potentially be increased, two being the minimum number necessary to identify this behavior.

At the molecular scale, an OR gate can be constructed from a PET system which emits luminescence when a receptor is occupied by any one of several guests, thereby blocking a PET channel. Thus the ideas employed for YES logic can be re-

applied here provided that the receptors are deliberately chosen to be poorly chemo-selective. A well-behaved OR gate should additionally have more or less the same high level of luminescence output when switched “on”. This condition is not always easy to satisfy in a rational manner. Molecule **10** [42] illustrates these points. The amino acid receptor within **10** successfully binds Ca^{2+} or Mg^{2+} , although with quite different stability constants (10^5 or 10^3 M^{-1} , respectively). Thus $10^{-3} \text{ M Ca}^{2+}$ or 0.5 M Mg^{2+} are sufficient to engage the receptor site and block PET from the receptor. Thus the nonselectivity of binding is sufficient for our present purpose, though it should be noted in passing that this receptor is selective enough to permit physiological monitoring of Mg^{2+} [43, 44]. Our purpose requires more than non-selectivity of binding: we need nonselectivity of the ion-induced luminescence response. Once either ion is in the receptor site, it arranges the ligating groups around itself into a coordination shell such that the conjugation between the amine and the benzene ring is cut off even though the two ions have quite different radii and charge densities. Thus the PET process is blocked to the same degree. In other words, the control of PET prevention in **10** is conformational rather than electrostatic.

**10**

NOR logic

NOR logic can be considered as an OR gate feeding into a NOT gate. This inversion of an OR action can be seen in Figure 1 with the appropriate truth table. Similarly a minimum of two inputs is required, but the number of input channels can be extended.

Our **11** [45] builds on the known ability of protonated pyridine units to quench the emission from fluorophores in their neighborhood [46]. The electron deficiency of such units makes them good acceptors in PET processes. Compound **11** possesses a 2,2'-bipyridyl unit which can be a receptor for H^+ , but it can also bind Zn^{2+} [47]. In either case the 2,2'-bipyridyl unit is rendered more electron-deficient. Hence, the fluorescence of the anthracene unit is quenched upon input of either ion in sufficiently high concentrations. The requirement for nonselectivity of the ion-induced luminescence response is not as stringent as for the OR gate described above,

provided that the quenching is efficient enough. More generally, **11** illustrates how integration of two logic operations can be achieved functionally within one molecule without resorting to physically “wiring up” two separate molecules—a much tougher proposition.

**11**

XOR logic

An exclusive-OR gate is one in which the presence of only one input out of two registers a high output value. Considering the two-input situation, presence of neither input or presence of both inputs gives a low output signal. This situation can be seen in Figure 1 along with its truth table. Another way of viewing this situation is that the gate compares the inputs and if they are different then an output 1 is given, whereas if they are the same an output 0 is derived.

This logic type proved particularly difficult to emulate at the molecular scale until Credi et al. provided the breakthrough [48]. Following a mechanochemical line of attack (see Section 5.3.1), an electron-rich macrocycle **12** serves as a “bead” sliding on a “string” which is made from an electron-deficient heteroaromatic **13**. The complex **12**·**13** is held together by charge transfer (CT) interactions. This same CT

**12****13**

interaction causes efficient quenching of emissions both from **12** and from **13**. Protons and Bu_3N are the two inputs and the fluorescence of **12** is the output for the present purpose. Application of protons alone, at sufficiently high concentration, causes protonation of the oxygen atoms in **12**, forcing the “bead” to slip off the “string”. Freed of the suffocating CT interaction, both **12** and **13** recover their fluorescence emissions. Interestingly, protonation of **12** does not perturb its emission compared with the neutral form. Thus the output becomes digital 1. Conversely, application of Bu_3N alone causes attachment to **13** via a strong CT interaction, again forcing collapse of the complex **12**·**13**. A strong fluorescence output (digital 1) is seen from the liberated **12**. Finally, simultaneous application of both inputs in stoichiometric amounts for acid–base neutralization results in the complex **12**·**13** being left untouched in its nonemissive state, i.e., digital 0 output.

XNOR logic

Exclusive-NOR logic is analogous to an XOR gate feeding into a NOT gate. The electronic symbol and corresponding truth table can be seen in Figure 1.

Controlled perturbation of a “bead-on-a-string” complex again provides entry into this logic type [49]. CT complex **14**·**15** has the necessary electron-rich and

electron-poor components except that, this time, the bead **14** is electron-deficient and the “string” **15** is electron-rich. A more critical difference compared with **12**·**13** is that the output is viewed as the CT absorption band. The virtually mutual exclusivity of CT absorption and component fluorescence provides a way to evolve XNOR logic systems from their XOR cousins. The two inputs are the application of reductive and oxidative potentials sufficient to cause one-electron reduction of **14** and to cause one-electron oxidation of **15** within complex **14**·**15**. In either case, the complex collapses and the CT absorption band dies with it. Thus the supply of either input on its own produces an output of digital 0. As we saw, the absence of both electrochemical inputs (both inputs at digital 0) preserves the complex **14**·**15**

and its signature CT absorption (output digital 1). Again the final row of the truth table is arranged with a neutralization of reductive and oxidative potentials of equal magnitude. The net potential of zero leaves complex **14-15** untouched with its CT absorption intact, i.e., output digital 1. Notably, the fourth row of the truth table is indistinguishable from the first row in this case.

INHIBIT logic

INHIBIT logic in its three-input manifestation is more complex than other logic types presented in previous sections, as can be seen from the electronic symbol and the corresponding truth table in Figure 1. A NOT gate confronts the third input signal before it can reach the AND gate. Thus, at first sight, a “wiring” of two molecular-scale gates is required. As mentioned under NOR logic, such challenges can be successfully sidestepped by functional, rather than physical, integration. In this instance we require the presence of the third input to disable the entire device. The powerful quenching influence of O_2 on relatively long-lived triplet states fits the bill. Phosphorescent bromonaphthalene is built into system **16** [45], which also contains a polyaminoacid receptor, not unrelated to that found in OR gate **10** described above, which launches a PET process to quench phosphorescence unless blocked by Ca^{2+} complexation. The AND logic action is completed by arranging for β -cyclodextrin to bind and encapsulate the bromonaphthalene phosphor [50] so that the excited state of the latter is protected from collisional triplet-triplet annihilation [51]. Thus, the presence of Ca^{2+} and β -cyclodextrin and the absence of O_2 is the condition under which phosphorescence output is observed from **16**.

The simpler two-input INHIBIT gate **17** was unveiled very recently by Gunnlaugsson et al. [52]. The disabling second input is, again, O_2 . Tb(III) complexes occasionally display luminescence which is quenched by O_2 because the metal-centered excited state is only slightly lower in energy than the triplet excited state of the aromatic ligand. The two-way energy transfer between these two excited states mixes them sufficiently for the usual O_2 -sensitivity of organic triplets, as seen in **16** above, to show up in the Tb(III) luminescence. The first input which supports luminescence is H^+ , which protonates the quinoline and shifts the absorption band into contact with the excitation wavelength. In other words, absorption is denied to **17** unless H^+ is present at sufficient concentration. Thus the line-like luminescence of Tb(III) is seen only if H^+ is present and if O_2 is absent.

16

17

ENABLED OR logic

A recent report from the Lisbon–Bologna collaboration shows how their AND logic gate (discussed under “AND logic”, above) can be expanded into three-input ENABLED OR logic systems [53]. The electronic symbol and corresponding truth table in Figure 1 illustrates its relative complexity. The expansion is achieved by noting that anionic micelles such as sodium dodecyl sulfate (SDS) present highly negatively charged surfaces to locally trapped fluorophores such as **5**. Such surfaces concentrate protons locally [54, 55]. Thus SDS above its critical micellar concentration serves as an enabler for protons, even at relatively high bulk pH, by concentrating them sufficiently to activate the process shown in Figure 5.

The last few examples clearly illustrate how photochemical systems can emulate integrated logic gates at the molecular scale. It is clear that more and more logic types will fall to chemists’ ingenuity in the coming months and years.

5.2.2 All-optical Input/Output

Multichromophoric systems

The NAND gate molecules **18** and **19** proposed by Birge [56] are designed to contain two input chromophores to which light can be directed. A retinal Schiff base derivative is used as the output chromophore whose absorption band is expected to shift upon electric charging of the porphyrin which is to serve as a charge integrator. The input chromophores are stated to be selectively excitable although their structures do not differ significantly in **18**. The electric charging upon excitation of the input chromophores is considered to arise from electron transfers (PET) in **18** and from internal charge transfer (ICT) in **19**. We await detailed information on these molecules in the primary literature before attempting any mechanistic discussion.

18

The donor–acceptor molecule **20** [57, 58] has been shown by Wasielewski and his colleagues to be capable of acting as an ultrafast molecular switch with potential logic capabilities. The two terminal porphyrin donor moieties are independently capable of reducing the central perylene tetracarboxydiimide acceptor moiety via PET. When only one porphyrin is excited by a femtosecond laser pulse, the absorption due to the perylene tetracarboxydiimide radical anion is seen. If both porphyrins are excited simultaneously by a higher-intensity laser pulse, two PET processes to the central acceptor can occur, giving a dianion, with a different absorption band. It is envisaged that this molecule should be capable of performing the AND logic operation if two different excitation wavelengths of light are used as inputs, and monitoring of the dianion absorption is used to read the output resulting from the various combinations of optical inputs. This is possible for molecule **20** since excitation of the perylene tetracarboxydiimide moiety will induce the first electron transfer process, and the second input wavelength can be the porphyrin absorption. Substitution of one of the porphyrins with a moiety capable of reducing the perylene tetracarboxydiimide in the excited state, but with a different absorption profile, should also function in this way. The extreme speed of such optical molec-

ular switches and gates is testimony to the lightness of their only “moving part”—the electron.

Systems based on spectral hole-burning

Not only can the technique of persistent photochemical spectral hole-burning (PSHB) be useful for molecular information processing but it has also been discussed for some time in the context of extremely dense frequency-domain optical data storage [59, 60].

Brief background

If molecules are embedded in solid hosts (e.g., in glassy or crystalline states) and temperatures are sufficiently low, sharp homogeneous absorption bands begin to show up within the broad inhomogeneous absorption band of the dopant [61]. A solute molecule and its noncovalently bonded solvent shell can be classified as a supermolecule [62]. Each solute molecule will thus create a unique supermolecule with its own arrangement of the solvent shell. Each supermolecule exists in a local energy well with a potential energy barrier which cannot be overcome at low temperatures. These supermolecules can show different physical properties—specifically, a spread in their absorption. In essence every supermolecule is different and can be addressed individually.

Selective irradiation of a given supermolecule will cause its photoconversion to another species. Hence its original spectral signature will disappear. This photochemically etched information is the spectroscopic “hole”, in that the essential profile of the absorption band remains but, at the precise frequency corresponding to the etching energy, a large absorption change will be observed. Monitoring this change allows for an information read-out process. This information can be re-read provided the hole persists [63], which is the case at low temperatures [64]. Single-molecule detection is thus possible via fluorescence [65] or absorption [66] detection.

Most frequently PSHB has been employed or studied in the context of data and image storage. The storage of information relies upon writing of information onto micrometer-scale spots. This hole-burning technique allows unique addressing of numerous domains within each spot, each of which represents one data bit (up to a density of 10^{12} bits cm^{-2}) [67]. An analogy would be a number of people, each with his/her own mobile telephone, in a single room. As well as these frequency-domain optical storage systems, the use of a controllable electric field provides the potential for even higher storage densities [68].

Spectral hole-burning and molecular-scale information processing

Wild [62, 69] described the potential application of spectral hole-burning in developing a parallel information processor by combining it with the Stark effect (the interaction of molecular energy levels with an applied electric field) and the interferometric properties of holography. Data stored in two-dimensional arrays can be directly combined in parallel, without the use of an external processor. A four-

dimensional space is effectively created with two geometrical dimensions from the sample along with a third dimension from the burning wavelength and the fourth from the electric field. A laser beam is split into reference and object beams. The object beam is overlapped with the reference beam at the sample, a chlorin guest **21** in a polyvinylbutyral matrix. The two phototautomeric forms of **21** involved in the key photochemical reaction are shown.

By synchronous exposure of the sample to object and reference beams and by adjusting the laser frequency and electric fields appropriately, holograms were obtained. Each hologram is thus associated with specific values of electric field and laser frequency. The image could be reconstructed by illuminating the sample with the reference beam alone. Specific images were selected by choosing the laser frequency and electric field strength used during the recording process. An applied electric field changes the shape of the spectral hole as it interacts with the dipole moments and polarizabilities of the guest molecules. Pairs of holograms can therefore be stored at the same optical frequency and with slightly different electric fields.

At the burning coordinates the recorded images can be constructed separately. The individually recorded holograms can be reconstructed simultaneously. This results in coherent superposition, the nature of which depends on the relative hologram phases selected during the recording process. By control of the hologram phase during recording, constructive or destructive interference of the hologram is observed. Thus, with the appropriate combination of holograms of two-dimensional objects, logical operations between data arrays can be performed with a new resultant image. The logical operation performed depends on the relative phase used during the recording process: constructive interference results in an increase in intensity where the images overlap and the images are added, and destructive interference results in a subtraction of the images [70, 71].

The amplitudes of each component add in the interferometric holographic operation. From these efficiencies truth tables can be derived by looking at corresponding pixel elements and employing a certain level of discrimination. Logical operations performed correspond to the OR, AND, and XOR functions. These operations are performed in parallel on the basis of individual pixels. Thus these systems demonstrate parallel information processing at the molecular scale.

5.3 Other Approaches to Molecular-scale Information Processing

5.3.1 Mechanochemical Approach

The classical mechanical device used for information processing is the abacus. Even today human operators perform arithmetical calculations at speed with these “beads-on-wires”. Molecular emulation of the form and function of the abacus could allow rapid switching speeds and calculation rates, with bead position and position read-out being performed by external physical stimuli rather than human manipulation and observation. Approaches to the type of materials suitable for use as thread and beads and to the manipulation and determination of bead position have been made via self-assembling rotaxanes [72].

Such rotaxanes incorporate a macrocyclic structure (representative of a bead) on an acyclic chain (thread), with bulky stopper groups at their ends to prevent dethreading. The position of the bead on the thread, and hence representation of information, is controlled by the incorporation of “stations” on the thread upon which the bead preferentially resides. Requirements of a successful system are that the bead can be controllably shuttled between stations by an external stimulus and that the position of the bead can be subsequently read out.

The problem of controlling the bead on its thread can be addressed by using the charge transfer interaction between π -electron-rich and π -electron-deficient aromatic rings. In particular the interaction of cyclobis(paraquat-*p*-phenylene) **14** with π -electron-rich aromatic rings [73] and the interaction of bis(*p*-phenylene)-34-crown-10 ether **22** with paraquat [74, 75] have been used.

22

In these cases **14** and **22** act as beads, threaded on stoppered polyether chains containing the π -electron-rich or π -electron-deficient stations. This noncovalent interaction simplifies the synthetic procedures necessary, as the unstoppered thread and its bead will self-assemble, and the resulting charge transfer complex can be stoppered with bulky terminal groups to give the functional rotaxane. Other suc-

cessful approaches include clipping an uncyclized bead which interacts with a thread station to its cyclized rotaxane and thermal “slipping” of the bead over the stoppers [72].

Using the bead **14**, a rotaxane has been synthesized which contains two π -electron-rich moieties, namely biphenol and benzidine [76]. The thread portion **23** of this rotaxane therefore contains two stations upon which the tetracationic bead can potentially reside. For such a device, stability of the bead at its preferred station must be considered. This implies that a large energy difference ($>kT$) between stations must exist at the operating temperature to prevent dynamic shuttling of the bead between the stations.

Manipulation of the bead in this instance is accomplished in one of two ways. Firstly and most successfully, an ionic stimulus can be used. When the benzidine nitrogens are protonated with $\text{CF}_3\text{CO}_2\text{H}$, electrostatic repulsion causes the energy bias between stations to switch and forces the tetracationic bead to translate along the thread; the bead then preferentially resides at the biphenol station. This situation can be reversed using pyridine. Secondly, the benzidine moiety can be electrochemically oxidized to give the corresponding radical cation, which again switches the energy bias, leading to preferential residence of the bead at the biphenol station. Electrochemical reduction restores the bias toward the benzidine station. In common with other systems [77], determination of the bead position can be made either

Figure 7. A light-driven molecular shuttle.

from NMR signals or by optical monitoring of the charge transfer bands due to two possible interactions of the bead and the interactions between the bead and spacing polyether chains.

Nakashima took up the challenge to build a light-driven rotaxane-based molecular shuttle **24** [78] (Figure 7). On photoirradiation of the aqueous solution with ultraviolet light a photoisomerization of the azobenzene unit from *E*- to *Z*- occurred, forcing the movement of the shuttle to a new station, a hydrocarbon spacer. Subsequent irradiation with visible light caused reversion to the *E*-form accompanied by movement of the shuttle to its original station. This cycle could then be repeated at will. Further development of this important system should reduce the timescale of switching.

In addition to these molecular shuttles, other dynamic supramolecular systems have been reported with the development of molecular trains utilizing catenanes [79], where one catenane ring can continually cycle around another via several stations. Sauvage and co-workers [80–83] reported electrochemically induced ring gliding in copper catenanes which exploits the differing preferred geometries associated with Cu(I)/Cu(II).

Figure 8. A directed graph with a unique Hamiltonian path, where circles represent vertices (cities) and arrows represent edges (routes).

5.3.2 Oligonucleotide Approach

Seminal work by Adleman demonstrated that molecular biological methods could be successfully employed to solve a mathematical problem [84, 85]. The problem he solved was a Hamiltonian path problem, in common parlance referred to as a travelling salesman problem. This is a hard computational problem for which no satisfactory algorithm is known allowing solution with electronic computers in polynomial time [86]. The potential of this DNA-based methodology relies on the inherent parallelism a DNA molecule affords.

The solution to Adleman's problem (Figure 8) is the correct combination of routes between several vertices (or cities), fulfilling several criteria. These are that the starting and finishing cities in the directed graph are defined, each city must be visited, each city can only be visited once, and there is a defined set of one-way edges (or routes) connecting different cities. A Hamiltonian path may not exist, if all the above criteria cannot be satisfied.

Different 20-residue oligonucleotide sequences (20-mers) containing unique, randomized sequences of A, T, C, and G bases were used to code for each of the cities. Selection of random sequences made it improbable that oligonucleotides associated with different cities would share long common sequences that might result in noncognate binding occurring (particularly during the ligation step). Each route was coded with a 20-mer, such that one-half (a 3'-10-mer) formed the Watson-Crick complement to half of one city, whilst the other half (a 5'-10-mer) could similarly anneal with the first half of the adjacent city. Thus neighbouring cities could be linked by the appropriate route.

Each route was phosphorylated at the 5'-hydroxy position, permitting the joining of the appropriate route 20-mer with the 3'-hydroxy position of another. Equimolar quantities of the complementary 20-mer of each city and each route were then mixed together in a single template-directed ligation step. The complementary 20-mers of each city served as splints to bring oligonucleotides associated with the compatible routes together for ligation. This reaction resulted in the formation of DNA molecules encoding random paths throughout the graph.

To implement the next step of the algorithm, the product of the previous step was

amplified by the polymerase chain reaction (PCR). Primers were used which bind to the ends of the DNA strand to promote the replicating action, by activating the enzyme. The primers chosen were such that they bound only to the 20-mers associated with the start and finish. The presence of both results in an exponential amplification in sequences terminating with the correct starting and finishing cities, satisfying the first criterion. Gel electrophoresis provided a means of separating the polyanionic, double-stranded DNA based on molecular weight. Isolation of the 140-basepair band gave a population of molecules satisfying the condition that exactly seven cities were visited. This set was then amplified and further purified.

The final step of the algorithm determined whether all the cities were visited, via use of combinatorial methods. This was achieved by affinity purification with biotin-avidin magnetic bead systems. Firstly, the double-stranded DNA product of the previous step was dissociated to give single-stranded DNA. Secondly, the microscopic beads were introduced upon which the complementary sequence to one of the cities was previously attached. Therefore sequences containing this city could specifically bind to it. Removal of the beads, washing, and releasing the bound strands then gave the molecules fulfilling part of the solution. This subset was further reduced by repeating this iteration sequentially with different sets of beads, each set containing the complement of a different city (start and finish cities had already been accounted for). The product of this step was PCR-amplified and run on a gel. The bands obtained demonstrated that these molecules encoded for the correct Hamiltonian path, proving that the route did exist. Absence of any bands would therefore mean that no appropriate path existed.

This type of problem is so complex that, with certain graphs containing less than 100 cities utilizing current algorithms it would take hundreds of years to solve [85]. Whilst electronic computers require exponentially increasing amounts of time to solve more complex problems, DNA would require a linear increase in time. However, whilst the time required to perform these calculations increases linearly, the quantity of material required for the purpose increases exponentially [87]. Despite the progress achieved, practical and theoretical obstacles to creating a DNA computer remain.

Theoretical limitations concern the versatility of DNA computers and their capacity to accommodate efficiently a variety of computational problems. DNA computing generated much excitement, mainly caused by the capability for massively parallel searches. This in turn showed its potential to yield tremendous advantages from the point of view of speed (10^{18} operations s^{-1}) and energy consumption (10^{19} operations J^{-1}), and could allow for an extremely high information density (1 bit nm^{-3}). A single strand of DNA can be likened to a string consisting of a combination of four different symbols A, G, C and T. Mathematically, this means that a four-letter alphabet can encode information, whereas an electronic computer uses only two digits, 0 and 1, for the same purpose.

DNA computation can be built on the large array of bio-operations, as exemplified in the previous case, which could be used to write programs [88]. A program will receive a tube containing DNA strands encoding information as input and output, either “yes” or “no” or a set of tubes. A bio-computation will consist of a sequence of bio-operations performed on tubes containing DNA strands. A rela-

tively simple solid-phase method for solving Hamiltonian path problems using DNA has been introduced. In this approach all, and only, the possible pathways are generated stepwise using molecules. Therefore, the entire procedure requires significantly less time than the previous one. Since its selection operation is not by the length of DNA, this method can be employed in other molecular applications using the DNA length.

DNA computation may hold the key for certain complex problems, where existing electronic computers are very inefficient and where massively parallel searches can be organized. Potential development of this field therefore relies on the recognition of algorithms better suited to these molecular methods. Lipton [89] suggested methods to extend this idea to solve other difficult problems, again relying heavily on the huge parallelism inherent in DNA-based computation. Various modifications of Lipton's model based on DNA manipulation have been systematically investigated.

Other approaches to DNA computation have been suggested, including a method to calculate the product of Boolean matrices containing positive numbers [90]. In the case of matrices containing real numbers, the manipulation of reaction conditions allows a quantitative calculation to be performed. This use of DNA to perform an analog calculation is a new approach to computing with DNA.

Besides this approach based on oligonucleotides, there have been some notable efforts by Lotan and co-workers to use the enzymic activity of polypeptides as logic gates [91, 92]. These are particularly interesting because enzymatic activity can be viewed as an amplification process.

5.3.3 Quantum Approach

The distinctive feature of a quantum computer is the ability to store and process superpositions of numbers [93]. This potential for parallel computation has led to the discovery that certain problems would be more efficiently solved on a quantum computer than on a classical computer [94, 95]. The most dramatic example is an algorithm presented by Shor [96], showing that a quantum computer should be able to factorize large numbers very easily. This would have a large social impact since the security of many data encryption systems relies on the inability of classical computers to factorize large numbers.

A quantum computational network can be decomposed into quantum logic gates [94, 95], analogously to the situation for classical computers. Quantum logic gates provide fundamental examples of conditional quantum dynamics, in which one subsystem undergoes a coherent evolution, which depends on the quantum state of another subsystem.

Experimental realization of a quantum computer requires isolated quantum systems that act as the quantum bits (qubits), and the presence of controlled unitary interactions between the qubits. As pointed out by many authors [97–99], if the qubits are not sufficiently isolated from outside influences, decoherences can destroy the quantum interferences that actually form the computation.

Nuclear magnetic resonance

Recently, nuclear magnetic resonance (NMR) techniques have been adapted as an approach to quantum computation. This has the attraction that most chemists are familiar with NMR spectrometers, though perhaps not with this adaptation. Quantum calculations rely on controlled time evolution of a system of coupled qubits. In the current context a qubit can be considered as a nuclear spin vector which in an applied magnetic field can spin in one of two states (α and β), equivalent to a digital 0 or 1. Qubits can exist in superposition states where they are simultaneously 0 and 1. Therefore, a system of qubits represents all possible values at the same time. When a quantum gate performs a function it operates on all the numbers simultaneously. For example, 32 qubits hold over four billion numbers and a quantum gate performs a function on all of them, whilst a normal computer works on one at a time. Qubits also have a property called entanglement. In a system with several qubits, changing or measuring one will simultaneously change the others. This property is used to “wire” together all the qubits in a quantum computer so that they act as a complete system.

Therefore the NMR computer consists of a molecule, which is the “circuitry”, and the NMR spectrometer, which acts as the gate array and provides a method of reading the answer. Application of the correct sequence of radiofrequency pulses therefore determines the operations the molecule can perform [100].

Gershenfeld and Chuang’s two-qubit system [101] uses an NMR machine and the protons in **25**. They demonstrated a nonlinear interaction between spins, a prerequisite for quantum logic gates. This was realized through the controlled-NOT operation (CNOT) which conditionally flips one spin based on the value of another [102]. This gate can be considered as a quantum XOR gate.

Laflamme et al.’s three-qubit system [103] is **26**. In this molecule the two carbon nuclei are in different chemical environments and therefore represent two qubits, whilst the proton serves as the third. Compound **26** therefore represents the binary numbers 000, 010, 011, 100, 110, and 111. A pulse of radio waves causes the nuclei to be thrown into the entangled superposition state, where they can act as qubits. The NMR machine then initiates the quantum computer program—a series of radiofrequency pulses that act like gates on the qubits and carry out the calculation. The superposition state is then collapsed to give an answer.

NMR techniques suffer an exponential drop in signal-to-noise ratio as the number of nuclei are increased; thus larger-scale implementation using the methodology outlined previously may be prevented. Other limitations associated with the scaling-up involve distinguishing qubits on a molecule by their chemical identities in larger molecules, the large number of molecules in solution required to perform the com-

putation, and the lack of a properly initialized starting state (e.g., all spin α). This latter problem arises from thermal equilibration between the two states corresponding to a Boltzmann-type distribution.

Cold trapped ions

Cirac and Zoller's [104] idea was that a set of N cold ions, interacting with laser light and moving in a trap [105, 106], provides a different physical system for implementation of a quantum computer. The key features of this system are that it allows the implementation of N -bit quantum gates between any set of ions (even nonvicinal ions), decoherence is made negligible during the whole computation, and the final read-out can be performed efficiently. In this proposal, the qubits are the ions themselves. The two states of the n th qubit are identified with two of the internal states of the corresponding ion, either the ground or excited state. Independent manipulation of each individual qubit was accomplished by directing different laser beams to each of the ions.

The quantum-controlled NOT gate with the trapped ions can be implemented by exciting the collective quantized motion of the ions with lasers. The coupling of the motion of the ions is provided by the coulombic repulsion which is the dominant interaction for small ion-ion separations of the order of a wavelength. The final read-out of the quantum register (state measurement of the individual qubits) at the end of the computation can be accomplished using quantum jumps with unit efficiency [107, 108].

Coupled quantum dots

Previously, the dipole-dipole interaction between the two qubits through magnetic dipoles (nuclear spins in an external magnetic field) was seen through NMR logic. Qubits can also be seen to interact through their electric dipoles (single-electron quantum dots). Mathematically the two cases are identical [109]. While the subjects of this subsection are not molecules as such, the relatively small size of quantum dots justifies their brief discussion here.

A quantum dot is a charge in a zero-dimensional space, an electron confined in an extremely small box. In the current context, presence or absence of an electron gives the requisite 1/0 states. Bate et al. [110] imagine a large two-dimensional array of devices that couple with their neighbors. Coupling may be achieved through short-wire connections or, preferably, by utilizing device-device interaction. Input/output of data occurs at the periphery of the array. They show an example of a system where the device (or cell) is a quantum dot and the coupling is electron tunneling between discrete levels. As examples of these proposed architectures, Randall [111] suggests multi-gate field-effect transistor-type devices. In these devices, a series of quantum dots is controlled by a third terminal added to each dot (called a "quantum logic cell"). By switching the tunneling current through the cell, various binary-output logic functions become possible. Because coupling using tunneling is short-range from the fabrication point of view, alternative coupling using long-range electrostatic interaction has been proposed. Bakshi et al.'s [112] system has elongated quantum dots (quantum dashes) arranged in an array. The

dipole moment in each dash is spontaneously polarized and the antiferroelectric phase appears. If a flip of dipole moments on individual dashes could be enforced, the resulting electrostatic perturbation would generate a domino-type response, flipping the dipole in the remaining dash which is viewed as cellular automata. Lent et al. [113, 114] elaborate on this idea using cells consisting of a central dot with four neighboring dots occupied by two electrons, instead of a dash. The cell has strong bistability of polarization which is encoded to the binary data, which are transferred by the inter-cell coulomb interaction as in the quantum-dash array. Arrays of AND, OR, and NOT become possible.

Nomoto et al. [115] have proposed another version based upon locally interconnected architecture, demonstrating AND/OR logic consisting of an asymmetric coupled quantum dot pair. The dots are coupled by both tunneling and the coulomb interaction. The device exploits the difference between the one-electron ground state and the two-electron ground state for the operation. In other words, the electron-number dependent ground state is viewed as a result of the operation. In their logic device, coupled quantum dots in which single-electron tunneling is influenced by electron–electron interaction were used. With occupation or not by a single electron in a quantum dot being equivalent to a bit 1 or 0, the device can be seen to perform (N)AND and (N)OR operations simultaneously. Data input/output was performed by irradiation/absorption of photons. The (N)AND and (N)OR operations were performed by the relaxation of the electronic system to the ground state, which depends on the number of electrons in the dots. When the device is constructed of semiconductor nanostructures, the main energy-loss channel is phonon emission from an electron. This scheme is particularly interesting because data processing is performed by electrons (fermions) whereas data input/output is done with photons (bosons).

5.3.4 Electronic Approach

As pointed out above, this approach has not yet yielded molecular-scale logic gates [116]. Nevertheless, its direct link to the culture of current computer industries appears to guarantee the greatest investment (intellectual and financial) so far. Also, there are many good discussions in the literature [6] and within this volume. We focus on a single recent achievement to put things in some kind of perspective.

For some time now, monolayers between two electrical conducting terminals (usually metallic) have given rise to asymmetric current–voltage curves indicating diode, or rectifying, behavior [12, 117, 118]. In some cases, the tip of a scanning tunneling microscope has been seen to act as one of these conducting terminals [119]. Electrical conduction across the single molecular thickness is generally ascribed to resonant tunneling where the Fermi levels of the metallic terminals are energetically close to the molecular frontier orbitals. The latter energy values can be derived from voltammetric measurements in solution. Though not without controversy, such work opens the way to interesting extensions.

In such an extension, Collier et al. [120] use a similar arrangement of a unimolecular layer sandwiched between metallic terminals with an additional barrier at

each molecular interface. Molecule **27** was used, but the actual chemical structure does not matter in this instance provided that surface-active viologen units are available. These viologen derivatives conduct through resonant tunneling provided they are contacted with a titanium surface and interrogated with a negative voltage (from the titanium side). However, the molecules are much poorer conductors at positive voltages, i.e., they exhibit a diode-like action. Furthermore, application of a positive voltage leads to irreversible oxidative damage which prevents any conduction, even upon returning to a negative voltage. The oxidative setting of the molecular switch in an “open” state is exploited to electrically reconfigure individual switches in an array.

27

Combinations of these switches, appropriately wired, lead to molecular logic gates. Collier et al. illustrate this by setting up two-input AND and three-input OR gates with a small array of switches containing several million viologen molecules in each. The excellent “on/off” discrimination in the output current can be ascribed to the diode-like nonlinearity in the switches when in their “closed” states.

The reconfiguring is illustrated by converting a three-input OR gate to a two-input version by oxidatively “opening” a switch in one of the input lines. This is somewhat reminiscent of certain programmable logic devices in silicon technology [13] where chosen links between individual logic gates are opened irreversibly so that the resulting device is customized according to the needs of the circuit designer.

In summary, molecule-based, but not molecular-scale, switches can be metal-lically wired to produce logic gates. However, this methodology is yet to be extended to truly molecular-scale counterparts.

5.4 Conclusion

We feel convinced that the diversity and depth of the approaches currently available for performing computational operations at the atomic/molecular scale offers a solid springboard for growth of the subject. The systems described so far may be rudimentary, the enthusiasm of some exponents may be excessive, and the criticism of some skeptics may be heavy: but at the end of the day, the subject will live or die according to the eventual uses to which the systems are put.

6 Antennas

Sebastiano Campagna, Scolastica Serroni, Fausto Puntoriero, Cinzia Di Pietro, and Vittorio Ricevuto

6.1 Introduction

Light energy from the Sun is vital for powering the living world. It is collected and used by plants to turn water and carbon dioxide into complex energy-rich molecules such as carbohydrates. Each year, more than 10^{17} kJ of energy from sunlight is captured and used by natural organisms (beside green plants, photosynthetic bacteria also concur to convert sunlight into more convenient forms of energy) to produce chemical fuels which provide the basis for life on Earth [1]. The basic process by which the natural photochemical energy conversion is accomplished is schematized in Eq. (1).

Such a reaction is highly endoergonic (as much as $114 \text{ kcal mol}^{-1}$ can be obtained from the opposite combustion reaction) and can only occur thanks to the energy input of the incoming photons.

The sunlight-generated fuels are used by photosynthetic organisms to drive their own metabolic processes, and also provide energy for higher organisms by supporting the food chain. Over billions of years, energy from the Sun also formed fossil fuels, which our civilization consumes at an increasing and alarming rate. Life and civilization are therefore basically founded on sunlight. To develop artificial systems capable of using the influx of solar energy on Earth to supply man's energy needs directly, providing a renewable and nonpolluting solution to man's increasing energy demands, therefore looks like a Holy Grail: taking the words of a famous lecture [2] delivered by one of the pioneers of photochemistry, Giacomo Ciamician, at the beginning of the 20th century, "... If our black and nervous civilization, based on coal, shall be followed by a quieter civilization based on the utilization of solar energy, that will not be harmful to the progress and to human happiness."

After a boost in research for artificial photosynthesis in the 1970s as a conse-

quence of the oil crisis, the field has been recently revitalized because of the environmental problems connected with release of carbon dioxide in the atmosphere from the burning of fossil fuels. It is now clear that man cannot tolerate the present conventional energy production processes any more. Looking at the present foreboding situation and at the outstanding recent developments in the field, it is conceivable that artificial photosynthesis may play a key role in providing a cheap and clean energy source in the 21st century [3].

The first functions an artificial photosynthetic system has to perform, similarly to the natural systems, are to collect solar light and to redirect it in the form of electronic energy to a specific site in its own structure (in the case of photosynthetic bacteria, for example, such a site is a properly organized pair of chromophores, called the special pair [4]). From this site a series of photoinduced electron transfer processes take place, with the final result of converting electronic energy into chemical (redox) energy. The absorption of light energy is performed by Nature by means of organized arrays of suitable chromophores; the funneling of the light energy absorbed by the various chromophores to specific sites is accomplished by migration of the electronic energy stored in each chromophore within the array, via a series of interchromophoric energy hopping and/or transfer processes. Early time-resolved measurements [5] showed that in natural systems this migration process is typically finished within ~ 100 ps, explaining the high, $\sim 95\%$, overall quantum yield of the process. More recently, it has been demonstrated that some of the individual energy transfer steps within the light-harvesting systems are in the subpicosecond timescale [6].

The arrays of molecular entities which perform the functions cited above (absorption of light and energy migration to a specific site) are called *antennas*. Like the other active components of the photosynthetic organisms, which have the role of performing other specific functions in the complex solar energy conversion scheme, the antenna is essential for the effective conversion of the solar energy input: its function, in summary, is actually to enhance the probability of catching the solar energy by increasing the molar absorptivity of the systems in the visible region of the solar spectrum. It has been estimated that the efficiency of conversion by the photosynthetic organisms of the input of solar energy into fuels (i.e., the ratio between moles of fuels produced and energy of solar rays incident on Earth) would be hundreds of times lower without the antenna effect [1]. This leads to an overall solar energy conversion which would have been insufficient to sustain life on Earth throughout the millennia if the antenna effect were not effective.

The aim of this article is to discuss the basic requirements that an antenna system has to fulfill and to summarize some examples of the various artificial antennas reported in the literature. For the sake of comparison, brief comments on natural antennas are also presented.

It should also be noted that, although the main interest in antennas comes from the search for an effective artificial photosynthesis, antennas may be relevant for any kind of application involving light-induced processes, such as luminescent sensors, photochemical reactions, and so on. The efficiency of any photoinduced process may actually be significantly enhanced by using suitable antennas, when the overall light energy incident on the system is considered.

Figure 1. Schematic representation of the LH2 antenna complex from *Rps. acidophila* [7]. Only bacteriochlorophyll molecules are considered, for clarity. The squares represent bacteriochlorophyll molecules which lie in the plane of the page. Their assembly is called the B800 system (see text). The rectangles represent the BChl molecules which are perpendicular to the plane of the page. These latter are in almost a face-to-face arrangement and constitute the B850 system.

6.2 Natural Antennas

The better-known natural antennas are the light-harvesting complexes of the photosynthetic bacteria, so our discussion will be limited to these species. A major breakthrough in the field has been the structural determination of the light-harvesting antenna complex (LH2) from *Rhodospseudomonas acidophila* in 1995 [7]. This structure (for a schematization, see Figure 1) is amazingly both simple and elegant: nine identical units, each consisting of two fairly short α -helical polypeptides and associated bacteriochlorophyll (BChl) molecules, combine into a ring. The helices are more or less perpendicular to the plane of the membrane. Within each unit, each pair of polypeptides coordinates three bacteriochlorophylls and one carotenoid. Two BChls are held near the periplasmic, carboxy-terminal end of the helices, and one is suspended between the helices near their middle. The antenna complex LH2 is therefore composed of two rings of bacteriochlorophylls, one set of 18 close to the membrane surface, in almost a face-to-face arrangement like a turbine wheel, and another set of nine all lying in the same plane which is perpendicular to the rings of the bacteriochlorophylls of the first type, in the middle of the bilayer. These nine chromophores are also arranged in the form of a wheel.

Because of their different chemical environments, the two sets of bacteriochlorophylls have different absorption and photophysical properties. The bacteriochlorophylls belonging to the larger wheel have the lower-energy absorption maximum at 850 nm (and are named B850) and the nine in the middle of the bilayer have the lower-energy absorption maximum at 800 nm (and are named B800). There are other significant differences between the two sets of pigments, as evidenced by a

series of spectroscopic studies [8]: the B800 BChl molecules are largely monomeric, whereas the B850 ones are strongly exciton-coupled [9], with the so-called exciton states delocalized over several (most likely four) BChl molecules. All the BChl are maintained in a fixed spatial relationship by the polypeptides. Carotenoids are also associated within the LH2 structure and have the function of contributing to the light-harvesting process [10] and of playing the role of photoprotecting species. The various BChl molecules absorb a significant proportion of solar light. The light absorbed by the B800 array is transferred to the B850 “wheel” within ~ 1 ps. Energy migration among the various exciton states of B850 then occurs on the 300 fs timescale [8].

LH2 is sometimes referred to as the *outer antenna*, because the energy it collects flows to its final destination through another antenna complex, named LH1, which immediately surrounds the reaction center, the site where the light energy has to be ultimately transferred and where charge separation takes place. The structure of LH1 is not known at the same level of definition as that of LH2, but an impressive result has recently been obtained by electron crystallography of two-dimensional crystals of the LH1 complex of *Rhodospirillum rubrum* [11]. This structure evidences a clear similitude between LH2 and LH1; LH1 is formed by 32 BChl molecules in the same arrangement as the B850 BChl molecules of LH2. Clearly, the “wheel” defined by the LH1 complex is much larger than that defined by the LH2 complex because of the larger number of molecules involved. Furthermore, LH1 absorbs at lower energy, so its BChl wheel is named B880. LH1 and LH2 are in a close contact (a shorter 30 Å distance between bacteriochlorophylls of the two complexes has been estimated), so that $\text{LH2} \rightarrow \text{LH1}$ energy transfer occurs with a time constant of 3 ps at room temperature. The reaction center (RC) is embedded within LH1, and energy transfer from LH1 to RC takes place with a time constant of 35 ps. This last step is therefore the slowest step of the entire process over the antenna network, which may be summarized in Eq. (2):

The overall energy migration within the antenna network to reach the reaction center is also schematized in Figure 2. The relatively slow rate of the final energy transfer to the RC is a consequence of the size of the RC protein, which prevents a short antenna–RC distance [8, 12]. It should also be borne in mind that the BChl molecules of B880 in LH1 are exciton-coupled like those of B850, and in view of the structural similarity between the two complexes, even in this case the exciton delocalization is probably relatively small and extends over about four BChl molecules [8]. This would imply that the energy is transferred from approximately eight sites of LH1 (each one composed of four delocalized BChl subunits) to the RC (assuming 1 RC per 32 BChl LH1 molecules).

To summarize, the natural photosynthetic processes occurring in bacteria are based on a clever modular design of the active subunits and on a series of downhill energy transfer steps. By indirect evidence, a similar organization appears to be present in the green plants [1, 8]. Ultrafast energy migration within almost iso-energetic subunits is used to transfer the energy within a single complex until it

Figure 2. Schematization of the overall energy migration within the antenna network to reach the reaction center. The small and large wheels represent the LH2 and LH1 complexes, respectively. For the LH1 complex, only the B850 system is represented.

reaches a site suitable for transferring the energy to a lower-energy complex, so allowing for a minimal loss. The various energy transfer steps mainly occur by the Förster singlet–singlet mechanism [13].

6.3 Artificial Antennas

6.3.1 Principles of Design

It should be borne in mind that the bacterial light-harvesting complexes described above have some differences from the plant light-harvesting complexes [1], although the basic principles of construction, in particular the modular approach, are common, as well as the occurrence of the sequential energy transfer steps via an energy cascade. This suggests that, just as Nature has responded in some slightly different

ways to the problem of converting solar energy, the design of effective artificial antennas can be tackled by a number of different approaches. Here we will be outlining the basic principles that appear to be necessary for designing an effective artificial antenna and in the next section we will discuss some representative examples of the artificial systems reported in the literature.

If an artificial system has to be developed, the obvious choice is probably to think of it as a modular system, as Nature did. This leads us to focus directly on the individual modules to be used (the building blocks). The requirements that the building blocks have to fulfill are the following: i) stability in the ground and excited states; ii) the capability to absorb solar light significantly [14]; iii) a relatively long-lived excited state, to allow energy transfer to occur with minimal loss of energy. In particular, point i) is even more important for artificial antennas than for natural ones, in that self-repairing processes, available in Nature, are difficult to reproduce in artificial systems.

After the building blocks have been selected, the next step is to connect them together. This is not a trivial point, in that suitable spatial connection is crucial for fast energy transfer. Of course, the connections should be selected to assure the necessary electronic coupling (through-space or through-bond) between the building blocks. In this regard, one can take advantage of both coulombic (Förster) [13] and electron exchange (Dexter) [15] mechanisms for the energy transfer. Nature makes use of noncovalent connections and the membrane elements guarantee the right arrangements among the chromophores. From a synthetic viewpoint, although supramolecular chemistry has made impressive progress recently as far as noncovalent made-to-order synthesis is concerned [16], noncovalent synthesis has not yet reached the necessary stage of development to allow the design of well-defined, controlled, and robust architectures to satisfy all the requirements of an effective antenna. Thus, covalent linkage is still probably the preferred choice.

The choice of connectors generally succeeds to the choice of building blocks. This is made clear on considering that the connectors have to allow interchromophore energy transfer fast enough to overcome the intrinsic decay rates of the individual chromophores. In other words, if the chromophores C_1 , C_2 , and C_3 are arranged in the series C_1 – C_2 – C_3 , so that the energy must flow from C_1 to C_3 , the energy transfer rate from C_1 to C_2 must dominate over the intrinsic excited-state decays of C_1 , and the same must hold for the couple of chromophores C_2 and C_3 . This is made evident in Figure 3. Because the chemical nature of the connectors affects the interchromophoric energy transfer rates, it is clear that connectors that are effective for antenna systems based on chromophores having slow intrinsic decays may be not suitable for antenna systems based on chromophores having shorter excited-state lifetimes. As a consequence, the connectors have to be properly designed for each type of antenna. The solution of the connector problem may also be related to the development of molecular wires [17] (see also Part 1, Chapters 1 and 3, in this volume).

For an artificial antenna to be effective, it should contain as much chromophore as possible. This point immediately calls for the development of suitable substrates to which the chromophores should be linked and/or of properly designed synthetic

Figure 3. Energy level diagram and restrictions on kinetic parameters for the series of chromophores C_1 , C_2 , C_3 . $k_d(C_n)$ represents the intrinsic decay rates for C_n , regardless the radiative or nonradiative nature of the processes; k_1 and k_2 are energy transfer rate constants.

approaches. Furthermore, to funnel the electronic energy to a specific point of the antenna, to which a charge-separation system should be connected, an energy gradient is necessary. As Nature uses essentially the same type of chromophore (porphyrins and derivatives), tuning their excited-state energies by means of environmental effects, a possible answer is to select building blocks whose properties are tunable by slight chemical modifications, and to insert these building blocks in the correct position of the array in order to create the desired excited-state energy gradient. The synthetic approaches needed therefore should be able to allow a topological control of the final array. This also introduces a further requirement, the tunability of the absorption and photophysical properties for the building blocks to be used.

The ideal sequence of choices which has usually been followed for the construction of artificial antennas up to now is shown in Figure 4. However, this sequence could be revolutionized if quite different approaches for the assembly of chromophores (e.g., self-assembly) should emerge.

All the antennas are easily schematizable, as in Figure 5 [18]. In this representation, each "floor" of chromophores contains identical subunits, and moving between floors one encounters chromophores which differ in excited-state energy, in such a way as to create an energy gradient. The chromophore at the basis of the array is the lowest-energy one, which plays the role of energy collector (energy trap, T). The energy gradient drives the antenna effect. The various "floors" of the artificial systems in this schematization play the role of the various "wheels" which assist the natural systems.

Figure 4. The sequence of choices usually employed to build up artificial antennas.

Figure 5. Schematization of an antenna system. † stands for the energy trap.

6.3.2 Examples

By definition, an antenna is a multichromophoric array in which the light energy captured by each active component (each single chromophore) is funneled by a series of elementary energy transfer steps to a single, specific site. So, two individual *actions*, light absorption and energy migration, are integrated to perform a multiple, more valuable *function*, the *antenna effect*.

Many systems, sometimes also very different from one another, have been designed to act as antennas. Here we will review only a few typical cases. We will focus on systems in fluid solution, leaving aside solid-state devices.

Figure 6. A typical europium cryptate featuring the antenna effect [19].

Although different synthetic approaches have been used, the experimental techniques employed to verify the properties of the systems are very often similar, and generally include steady-state and time-resolved absorption and luminescence spectroscopy.

Small antennas: lanthanide complexes

Maybe some of the simplest antennas are lanthanide complexes containing chelating polypyridine ligands, such as the Eu(III) cryptates developed by Lehn and co-workers [19]. In these simple antennas, the role of light-harvesting units is played by the N-heterocyclic ligands, which transfer the excitation energy in a sub-picosecond timescale to the lanthanide cations, which ultimately emit the collected energy with a high luminescence quantum yield (Figure 6). In spite of their simplicity and of the similarity of these systems to usual coordination compounds such as $\text{Ru}(\text{bpy})_3^{2+}$ ($\text{bpy} = 2,2'$ -bipyridine) and analogous species [20], in which the light absorbed by the ligand is also transferred to lowest-lying, luminescent, metal-to-ligand charge transfer (MLCT) states, we decided to include these lanthanide compounds in this chapter because they exemplify very well the importance of the antenna effect: in fact, the “free” lanthanide cations had previously been known to exhibit very good luminescence properties (quantum yields close to unity under certain conditions) but they were very poor absorbers, so their interesting photophysical properties remained almost useless. Light energy absorption is accomplished by the ligands in the cryptates, and the electronic energy is transferred successively to the lanthanides, making the whole species at the same time good absorbers (although usually only in the UV region) and emitters.

Following the initial reports of the antenna effect in lanthanide cryptates, many other lanthanide complexes containing additional chromophoric ligands have been investigated and found to be useful as luminescent labels for biological substrates, and in general as sensors based on luminescent properties [21].

Polymer-based antennas

Many artificial antennas have been based on polymers containing chromophores as appended photoactive units. An example of this class is the series of antennas developed by Guillet and co-workers [22]. In these species the energy traps are condensed aromatic hydrocarbons such as naphthalene derivatives to which the other (peripheral) chromophores, usually also of aromatic nature, transfer the excitation energy. Guillet's antennas are water-soluble polyelectrolytes, and have been termed *photozymes*, i.e., artificial photochemical enzymes, in that the antenna effect is used to amplify the photodegradation ability of the energy trap with regard to various hydrophobic substrates (pollutants) which are surrounded by the polyelectrolyte arrays in water solution, giving rise to a microheterogeneous photocatalysis. Similar antennas have been employed recently by the same group to evolve hydrogen from water under irradiation [23].

The approach based on derivatized polymers with appended chromophores has also been developed by Meyer and co-workers [24]. They used as chromophores polypyridyl complexes of Ru(II) and Os(II) which have high absorptivities in the visible region based on intense MLCT bands. An early synthetic strategy [24a] involved attachment of the chromophores to polystyrene by an ether linkage (Figure 7a). Successively [24b], the authors developed a new route based on amide linkage (Figure 7b), finding a dramatic enhancement in the ability of the polymeric arrays to promote intrastrand energy transfer. In a typical preparation, the amide polymer was obtained from a 1:1 styrene-*p*-aminomethylstyrene copolymer of polydispersity

Figure 7. Chromophores used as the photoactive appended subunits in Meyer's light-harvesting soluble polymers [24].

1.5 and an average of 16 repeating units. The amide link was formed by reaction with the acid-derivatized complexes, $[M(b)_2(b-COOH)](PF_6)_2$ ($M = Ru, Os$; $b = bpy$; $b-COOH = 4'$ -methyl-2,2'-bipyridine-4'-carboxylic acid) by using standard coupling conditions. A mixed polymer was prepared by sequential coupling, first with the $Os(II)$ complex (which is less reactive) in a limited amount and then with the more reactive $Ru(II)$ complex to fill all the free polymeric sites. In the mixed polymers, containing the lower-energy Os -based chromophores and the higher-energy Ru -based ones in a 3:13 ratio (so therefore the $Os(II)$ chromophores act as the energy traps), triplet-triplet energy transfer from excited Ru chromophores to the Os ones occurred with efficiency higher than 0.90 in acetonitrile solution.

It was pointed out that energy transfer from $*Ru$ to Os requires two processes: $*Ru$ -to- Ru energy migration (a self-exchange process) and the actual energy step from $*Ru$ to a nearby Os . For both processes the rate constants exceeded $2 \times 10^8 \text{ s}^{-1}$ for the amide-linked polymer, whereas in the ether-linked polymer the rate constant for intrastrand energy migration from $*Ru$ to Ru was orders of magnitude slower. The rate constants for the amide-linked species, coupled with the relatively long intrinsic lifetime of the $*Ru$ chromophores (910 ns), accounts for the ability of the polymer arrays containing the amide-linked chromophores to act as efficient antennas. The reason for the different behavior of the ether-linked and amide-linked arrays lies in the direction of the excited-state MLCT dipole of the chromophores involved in the energy transfer processes. This dipole is directed toward the polymer backbone in the most effective amide-linked antenna systems, whereas it acts out from the polymer backbone in the less efficient ether-linked arrays. This difference affects the electronic coupling between donor and acceptor sites of the energy transfer and migration processes. This finding demonstrates that in polymer-based antennas, slight modifications in the chromophore linkage may have large effects on the antenna performance. Recently, the same group also used poly(amino acid)s as polymer backbones to construct antenna systems [25].

Interesting antenna systems based on polymers have also been designed by Fox and co-workers [26]. They prepared a series of well-defined block copolymers labeled with aromatic chromophores and demonstrated that directional singlet energy migration across the block interface takes place, whereas extensive exciplex formation, a decay channel which dissipates electronic energy in flexible polymers, is strongly inhibited in these special polymers.

Within the class of antennas made of chromophores appended to polymers, there may be included the quite peculiar systems developed by Valeur, Lehn, and co-workers in a series of intriguing papers [27]. These species are based on β -cyclodextrins (which may be considered as cyclic oligomers) containing seven 2-naphthoxyloxy chromophores as substituents appended to the lower rim (Figure 8). In these systems, and in general in artificial antenna systems containing a large number of identical chromophores, an interesting problem to be considered is whether excitation hopping between identical units can occur in a truly chaotic fashion. By using fluorescence anisotropy in low-temperature glasses, the authors demonstrated that solvation heterogeneity causes inhomogeneous broadening in the spectrum of the chromophores, and this drives the energy hopping in the systems toward the lower-energy chromophore(s). Such an energy hopping occurs in the

Figure 8. Schematic representation of the cyclodextrin-based antennas [27].

systems studied with an average rate constant of $2 \times 10^9 \text{ s}^{-1}$ [27c]. When the cyclodextrin cavity encloses a merocyanine dye, a species having an excited state lower in energy than the naphthoyloxy chromophores, the light energy absorbed by the chromophores of the cyclodextrin rim is transferred to the merocyanine pigment with a quantum efficiency close to unity [27d]. The authors have also performed chemical reactions of substrates enclosed in the cavity, powered by the energy absorbed via the cyclodextrin antennas [27e].

Multiporphyrin arrays

Because Nature elected porphyrin derivatives as components of the natural antennas, it cannot be surprising that many artificial antennas are based on these chromophores. This represents surely the largest class of artificial antennas studied. Even for this class, we discuss just a few representative examples [28].

In a series of elegant and fascinating papers, Lindsey and co-workers developed a set of porphyrin building blocks and used them in a modular approach for the construction of a large series of light-harvesting arrays having highly-controlled geometries [29]. The porphyrin building blocks were facially encumbered to enhance solubility in organic solvents, were employed in defined metallation states (free base or zinc chelate), and carried peripheral functional groups such as iodo or ethyne for joining the porphyrins via covalent bonds by means of highly efficient hetero-coupling reactions. Figure 9 depicts a star-like pentameric array, together

Figure 9. Examples of star-like (top) and linear (bottom) arrays synthesized by Lindsey and co-workers [29].

with a linear array of four porphyrins and one accessory pigment. The latter array can be regarded both as an antenna and as a molecular wire. The quantum efficiency of energy migration from the high-energy boron–dipyrrole pigment through the medium-energy zinc porphyrins to the low-energy free-base porphyrin is 76 %, while the quantum efficiency of energy transfer from the peripheral, high-energy zinc porphyrins to the central, low-energy free-base porphyrin in the star-like pentameric array is quantitative. The effect of the geometry on the energy transfer efficiency was also investigated in variously arranged trimers and dimers. The mechanism of the energy transfer is in all the cases through-bond, as clearly shown by the dependence of the energy transfer rate on the nature of the linker, orbital tuning, and linker location [30].

Some of the largest light-harvesting arrays introduced by this research group, in collaboration with the groups of Birge, Bocian, and Holten, are nine-chromophore species containing a central porphyrin (free base or zinc-metallated) [31a], which act as the energy sink, and eight peripheral boron–dipyrrole accessory pigments (Figure 10). It was demonstrated that the light absorbed by the eight accessory pigments is transferred to the central subunit (the sink) with a quantum efficiency which exceeds 85 %, with an average rate constant of $5 \times 10^{10} \text{ s}^{-1}$. Quite recently, even light-harvesting arrays composed of eight porphyrins and one phthalocyanine acting as the energy trap have been reported [31b].

Lindsey, Donohoe, and co-workers also developed a matrix-formulated eigenvalue/eigenvector approach, using empirical data from a small set of prototypical molecules, to predict the quantum efficiency of energy migration in a variety of arrays as a function of rates, competitive processes, and architectures [32]. Following this approach, they demonstrated, among other findings, that:

- 1) branched and cyclic array architectures exhibit higher quantum efficiencies than linear architectures with an equal number of chromophores;
- 2) large improvements are achieved when energy transfer is directed by a progressive downward cascade in excited-state energy; and
- 3) the most effective light-harvesting arrays are those in which isolated pools of donors each have independent paths directly to the terminal energy collectors.

Of great interest is the recent coupling of some of the above-mentioned multiporphyrin antennas with the charge-separation artificial systems mastered by Gust, Moore, and co-workers [33]. This coupling led to the synthesis of one of the first effective artificial photosynthetic antenna–reaction center complexes (Figure 11). As revealed by time-resolved absorption and emission studies, excitation of any peripheral zinc porphyrin moiety (P_{ZP}) in 2-methyltetrahydrofuran solution is followed by singlet–singlet energy transfer to the central zinc porphyrin with a time constant of ~ 50 ps. The excitation is then transferred to the free-base porphyrin in 240 ps, and this latter species decays by oxidative electron transfer to the fullerene with a time constant of 3 ps. The $(P_{ZP})_3\text{-}P_{ZP}\text{-}P^{\bullet+}\text{-}C_{60}^{\bullet-}$ charge-separated state thus formed has a lifetime of 1330 ps, and is generated with a quantum yield of 0.7, based on the light absorbed by the zinc porphyrin antenna [33a].

Figure 10. A nine-chromophore species made of eight peripheral boron–dipyrrole pigments and one central porphyrin, acting as the energy sink [31a].

A representative example of multiporphyrin species in which the subunits are assembled by relatively weak coordination links is the three-chromophore species studied by Hunter and Hyde (Figure 12). In this system, the light absorbed by the zinc porphyrins is partially transferred to the free-base porphyrin subunit [34].

Dendrimers

In the very last few years, a molecular architecture which has received more and more attention in view of the construction of artificial antennas is that typical of dendrimers. Dendrimers are highly branched molecules which resemble the shape of

Figure 11. An antenna–reaction center complex [33a]. For details, see text.

a tree (*dendrimer* comes from the term *dendron*, the Greek word for tree, and *polymer*) originating from a core subunit and evolving into three dimensions [35]. Within their globular shape, subunits (and species) of various generations may be identified in the dendrimer structures. Without any doubt, the fact that the convergent and/or divergent synthesis of dendrimers allows assembly, in relatively few synthetic steps, of a large number of subunits (i.e., chromophores) in a restricted space and with a high topological control, is quite attractive for antenna designers. The peculiar characteristics of dendrimer molecules as far as the design of antenna systems is concerned have also been faced from a theoretical viewpoint [36].

Figure 12. Multi-chromophoric species assembled by weak coordination bonds [34].

Probably the largest class of light-harvesting dendrimers investigated up to now is constituted by the dendrimers based on Ru(II) and Os(II) polypyridine complexes, and the most extensive studies within these species involve the systems containing 2,3-bis(2-pyridyl)pyrazine (2,3-dpp) as bridging ligands [37, 38]. The synthetic approach is based on chelating ligand protection/deprotection iterative steps, developed within the framework of the so-called *complexes as ligands/complexes as metals* strategy [39]. Figure 13 shows the metal ions and the peripheral and bridging ligands mostly used in the course of this study, as well as their graphical representation, and Figure 14 schematizes the iterative synthetic strategy [37g, 38]. Dendrimers containing up to 22 chromophores have been synthesized by this approach [37c,g,i]; such species represent the dendrimers of the third generation within this particular series, and are characterized by a huge light absorption which extends throughout all the visible region (ϵ exceeds $2 \times 10^5 \text{ M}^{-1} \text{ cm}^{-1}$ at the visible absorption maximum, around 550 nm, and is still significant even at 750 nm). Such species are probably some of the best artificial antennas ever reported as far as the cross-section with sunlight is concerned. The MLCT excited-state levels of the various subunits constituting the dendrimers can be quite different from one another, as a function of the metal ion, of its immediate coordination sphere, and also, although to a minor extent, of its second coordination sphere; as a consequence, the excited-state energies of the various subunits depends on their composition and on their position in the array. This allowed the authors the opportunity of generating energy gradients within the dendrimers and of obtaining efficient energy migration

Figure 13. Structural formulas and schematic representation of some components used for the construction of light-harvesting metal-based dendrimers [37, 38].

among the “shells” of suitably designed dendrimers (see Figure 15) [38]. The complete topological control of the systems, a consequence of the synthetic approach, can actually translate into different, made-to-order energy migration patterns within the dendritic arrays. Several examples of such different energy migration patterns have indeed been obtained [38, 40]. The mechanism of the energy transfer steps has been proposed to be triplet–triplet electron exchange (Dexter-type), which is typical of photoinduced energy transfer in multicomponent species containing heavy transition metal coordination compounds [41]. The photophysical studies showed that energy transfer between nearby chromophores occurs with unitary efficiency and within a sub-nanosecond timescale, whereas energy transfer between indirectly connected chromophores has poor efficiency. Therefore, when a correct energy cascade is not obtained and endoergonic energy transfer steps are interposed in the energy pathway to the trap, as occurs in some of the largest dendrimers, the energy migration processes have poor efficiency. The situation is summarized in Figure 16. However, the authors indicated that suitable modifications in the peripheral ligands could permit to overcome this problem [38].

Purely organic light-harvesting dendrimers have been prepared by Moore and co-workers [42]. In these systems (Figure 17), the light absorbed by the peripheral chromophores (phenylacetylene monodendrons) is transferred to the core (perylene) via a coulombic mechanism. The efficiency of the process depends on the

Figure 14. Iterative synthetic strategy for metal-based dendrimers [38].

generation of the dendrimers. As expected, the quantum efficiency decreases with increasing generation. Compound **1** represents a particular case, in that the excitation energy is funneled to the focal point very efficiently (around 98 %), compared with the dendrimers of corresponding dimension of the series **2–7**. In contrast to

Figure 15. Energy migration pattern across dendritic shells in metal-based dendrimers. In the species represented, all the building blocks contain Ru(II) chromophores and the energy migration from the center to the periphery is quantitative [38].

monodendrons **2–7**, in fact, **1** possesses a variable monomer type at each generation which creates an energy cascade. The ultrafast energy transfer (calculated rate constant for energy transfer from periphery to the core in **1**, $1.9 \times 10^{11} \text{ s}^{-1}$) in this antenna is therefore explained by the presence of the energy gradient.

Other totally organic light-harvesting dendrimers have been developed by Fréchet and co-workers [43]. These species (Figure 18) typically contain coumarin 2 as the donor terminal chromophores and coumarin 343 as the acceptor focal dye. Favorable intramolecular charge transfer takes place in the excited state of these dyes, and this accounts for their high extinction coefficients and high dipole moments, which enhance the dipole–dipole interaction leading to fast singlet–singlet energy transfer via a coulombic mechanism. The energy transfer is thus highly efficient in the first three generations (at least 97 % of quantum efficiency for the process was calculated), and remains significantly efficient for the fourth-generation species (86 %).

Morphology-dependent antenna properties in dendrimers have been reported by Jiang and Aida [44]. They synthesized and investigated a series of dendrimers, of general formula $(L5)_n P$ ($n = 1–4$) having a porphyrin (P) as energy collector, which bear different numbers (n) of five-layered dendron subunits (L5) at the *meso* position of the central porphyrin (Figure 19). Upon irradiation of the dendron subunits in dichloromethane at room temperature, $(L5)_n P$ showed an intramolecular singlet energy transfer which leads to excitation of the central porphyrin core. It was found that tetrasubstituted $(L5)_4 P$ with a spherical morphology exhibited a much higher energy transfer quantum yield (80 %) than the partially substituted $(L5)_1 P$ – $(L5)_3 P$ species (32 % in the most favorable case). Fluorescence depolarization studies of

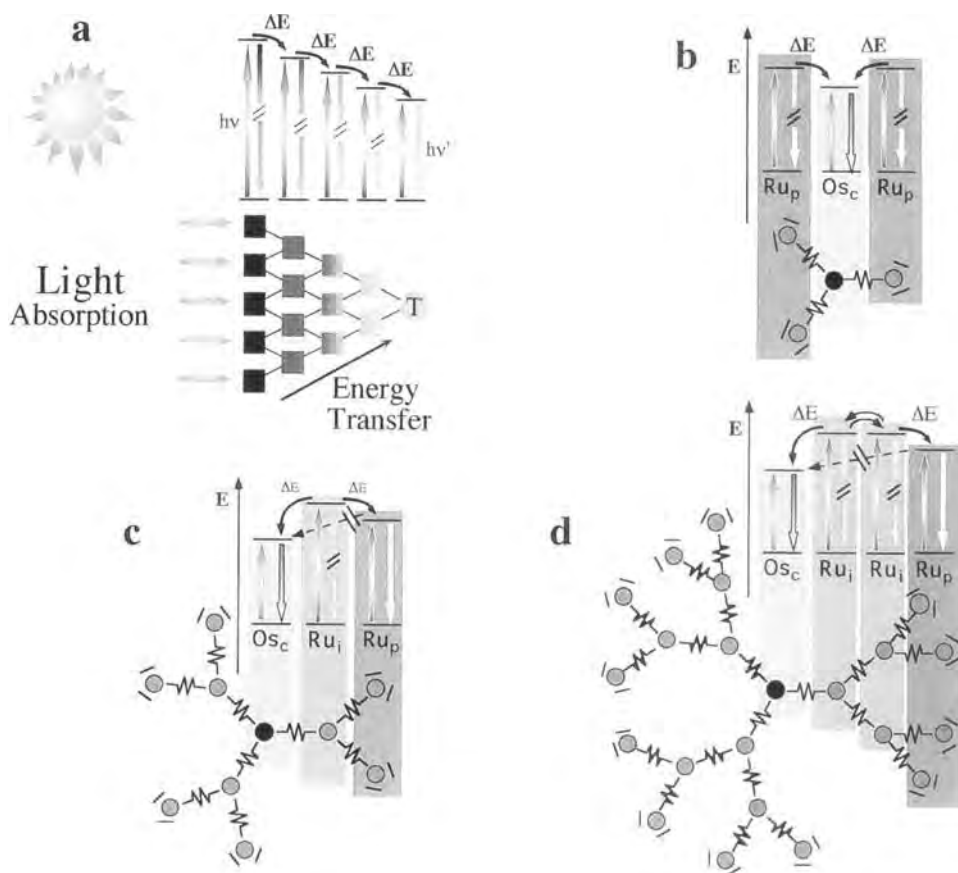

Figure 16. Schematic representation of a) a generic light-harvesting system and b) energy migration patterns for a tetranuclear compound, c) a decanuclear compound, and d) a docosanuclear compound containing one Os(II) species at the center and Ru(II) chromophores in intermediate and peripheral positions. In decanuclear and docosanuclear species, the intermediate chromophores have excited-state energies higher than those of both central and peripheral chromophores. As a consequence, uphill energy transfer steps are present for the energy migration from the peripheral chromophores to the central one and the overall process has poor efficiency [38].

(L5)₄P showed that the excitation energy migrates very efficiently over the various dendron units within the lifetime of the excited state. The four dendrons therefore behave as a single, large chromophore surrounding the energy trap. Consequently, the probability of energy transfer to the porphyrin core may be enhanced.

This hypothesis is schematized in Figure 20 and suggests an interesting similarity between the behavior of this type of antennas and the “wheels” of the natural photosynthetic systems (see above). The energy hopping between the various dendrons enhances the overall efficiency of the antenna, like the way in which ultrafast energy migration within the various chromophores arranged as wheels of LH2 and

Figure 17. Schematic representation of the light-harvesting dendrimers prepared by Moore and co-workers [42].

Figure 20. Schematic representations of photochemical events in aryl ether dendrimer porphyrins of spherical (left) and nonspherical (right) morphologies [44].

LH1 systems allows for a quite efficient energy transfer to the reaction center in the natural systems [8].

Stewart and Fox prepared a series of polyether dendrimeric segments (dendrons) end-capped with various chromophores such as pyrenyl and naphthyl groups. They used these species to investigate the possibility of quenching the aromatic chromophores by a suitable electron donor (e.g., a 3-(dimethylamino)phenoxy group), when it was covalently attached to the dendron focal point. The occurrence of the excited-state quenching of the chromophores definitively demonstrated substantial electronic coupling between appended chromophores and quenchers across the dendritic framework [45]. This is a somewhat unusual antenna, anyway, because energy transfer among the chromophores is not necessary to the process.

Miscellaneous

Many other systems, not included in the classes discussed above, are of interest as far as the development of artificial antennas is concerned. Among them, we would like to recall the trichromophoric species developed by McGimpsey and co-workers [46], in which phenyl, naphthyl, and phenanthryl groups are linked by adamantyl and methyl ester bridges. The authors demonstrated that energy migration from the highest-lying chromophore to the lowest-lying one occurs by sequential singlet–singlet and/or triplet–triplet energy transfer steps. Another interesting system is the light-harvesting bilayer membrane studied by Kimura and co-workers [47]. This latter system is composed of two amphiphiles: one having an antenna group (containing *N*-ethylcarbazoyl chromophores, ECz) and the other having an energy-accepting group (an anthryl chromophore) and an electron-accepting group (a viologen). It was demonstrated that efficient energy migration among ECz groups occurs in the membrane until it reaches an ECz which is close to the anthryl group. Then energy transfer from the excited ECz to the anthryl chromophore takes place, and the excited anthryl group successively reduces the viologen electron acceptor. The quantum yield of the overall process depends of course on the ratio of the various

components. However, the number of possible energy migration steps among the ECz molecules, calculated from experimental data and computer simulation, is 78. This figure looks promising for possible developments of this approach.

6.4 Concluding Remarks

In this report we have attempted to summarize briefly the basic principles of construction and functioning of the natural antenna systems, and we have pointed out some of the factors that one should carefully consider in designing artificial antennas for photochemical energy conversion. Then we presented selected examples of different types of artificial antennas recently reported in the literature. Far from pretending to be exhaustive, this list tends to be just an example of the ingenuity of the chemists and of the large and increasing efforts devoted to this field in the last few years. We mainly examined antennas which have been somewhat arbitrarily classified as soluble polymers with appended photoactive subunits (including the special case of cyclodextrin-appended chromophores), multiporphyrins, and dendrimers. Various mechanisms have been found to be responsible for the antenna effect in the different systems, with singlet–singlet (Förster and Dexter) energy transfer usually dominating the purely organic antennas and triplet–triplet energy transfer (mostly of the Dexter type) governing the processes for systems containing heavy transition metals such as Ru(II) and Os(II). This variety of artificial antennas and possible mechanisms, instead of suggesting uncertainty over which systems should be preferred, strongly indicates that there is not a single answer to the problem of designing efficient antennas, and the exploitation of multiple solutions certainly will enrich our possibilities.

On the basis of the studies reported in the last few years, it is clear that the recent significant progress both in mapping the natural systems and in designing sophisticated artificial systems has been made possible by the recent notable advancements of experimental techniques and made-to-order synthesis. Because both the experimental techniques and made-to-order synthesis are continuing to improve fast at the moment, further impressive developments in the field are expected in the near future [48], so bringing the photochemical conversion of solar energy closer.

14. The emission spectrum of the sun consists approximately of 9 % UV light, 40 % visible, and 51 % IR [1]. Only UV, visible, and a small fraction of the near-IR can cause electronic excitation. Furthermore, we have to take into account that the excitation energy collected should be enough to drive the chemical reactions we would like to use to store the solar energy. Therefore, any practical photochemical solar energy conversion system has to be based on visible light absorption.

 48. For example, artificial antennas based on noncovalent interactions can contribute extensively to the field. A typical recent case is reported in Ref. [49]. Other, still rarely considered, aspects of the natural systems could also play a role in the development of artificial systems. In this regard, of particular interest appear to be some investigations [50] dealing with the design of artificial light-harvesting systems which may spontaneously evolve toward greater efficiency under light illumination, a feature that at the moment remains mostly peculiar to the natural systems.

7 Memories

Masahiro Irie and Kenji Matsuda

7.1 Introduction

Information storage technologies, which provide high memory density, high capacity, and fast access, are indispensable to a highly developed information-based society. Although magnetic recording media such as magnetic tapes and hard disks have been used in mass memories, they are being challenged on several fronts with optical recording. Optical digital recording utilizes focused laser light to effect some optical property changes in the memory media which can be subsequently read back by the laser. The memory spot size can be reduced to as small as the wavelength of light. Therefore, the area memory density is higher than that of conventional magnetic recording. Optical digital recording is one of the most promising information storage technologies.

Although it has long been a dream of organic photochemists to use organic molecular materials as the optical memory media, the media mainly developed so far have been inorganic ones, which utilize the magneto-optic (MO) effect or phase change (PC) as the basis of optical recording. Nowadays, the situation is dramatically changing. CD-R (compact disk—recordable) disks which use organic dyes as the memory media have been developed and widely accepted as data storage as well as audio–video recording media. The number of CD-R disks supplied to the worldwide market in 1999 was as large as 2×10^9 , which was similar to the number of floppy disks. CD-Rs are compatible with CDs and CD-ROMs and the memory density is 650 MB. A new version, the DVD-R (digital versatile disk—recordable), has a density as high as 3.95 GB. The memory layer of a CD-R is prepared by spin-coating the organic dyes on the polycarbonate disk covered with gold or silver and used as the memory layer. The coated dyes are photoexcited with the focused laser light and decomposed thermally as well as photochemically. The decomposition of dyes results in changes in the shape and the refractive index of the recorded areas, which induce the reflection changes. The reflection changes can be read out by the laser. Organic dyes are the third generation of organic molecular materials, which

are used practically in opto-electronic devices (the first generation was liquid crystals; the second, organic photoconductors).

In principle, any kinds of organic dyes which undergo photochemical reactions by irradiation with visible laser light (635–830 nm) can be used as the memory media. The photochemical reactions can be detected by changes in refractive index as well as in absorption properties. Although most of photochemical reactions are irreversible, some organic dyes undergo reversible photochemical reactions (*photochromism*) and the photochromic dyes are potentially applicable to erasable optical memory media.

In this chapter the properties of organic molecules which are potentially useful as archival digital optical memory media, mainly erasable media, will be described. The memory media which require wet development/fixing processes will not be mentioned. Photopolymers and photoresists are also beyond the scope of this chapter.

7.2 Irreversible Memory Media

In the 1960s various types of photosensitive organic molecular materials were developed in an attempt to apply them to non-silver photographic systems. Although those materials and processes cannot be directly applied to modern digital optical memory systems, it is worthwhile to note them because useful basic ideas for constructing photosensitive systems were involved. Typical examples are shown in Table 1. In the first case the colored species are formed by radicals, which are produced by the electron transfer reaction from photoexcited amines to tetrabromomethane (Scheme 1) [1–3]. The tetrabromomethane can be eliminated from the systems just by heating. Thus, photogenerated images are fixed by heating. Although relatively high-sensitivity systems were developed, instability during storage prevented their practical use.

In the second case a violet-colored species (crystal violet) is produced by the photogenerated imidazole radical (Scheme 2). 1,6-Hydroxypyrene which is produced from 1,6-pyrenequinone by visible irradiation quenches the imidazole radical, and the system is fixed.

Other interesting photosensitive materials are alkylborates of cyanine dyes [5, 6]. An electron transfer from the alkylborate anion to the photoexcited cyanine dye causes the decomposition of the alkylborate to produce colorless alkyl-substituted cyanine dye derivatives (Scheme 3). The color of the cyanine dyes is bleached by photoirradiation. By mixing three kinds of alkylborates of cyanine dyes, yellow, magenta, and cyan, with vinyl monomers it is possible to construct a full color printing system.

As described in Section 7.1, a modern digital optical memory system, the CD-R, uses organic dyes as the memory layer. The dyes used are shown in Figure 1. All these dyes have absorption tails around 780 nm, where the recording laser has the emitting line. At the absorption tails the dyes show the maximum refractive index

Scheme 2.

changes. Therefore, their decomposition by laser light induces large changes in the refractive index or the reflection in the recorded area. At present much effort has been put into developing dyes suitable for DVD-Rs, which have absorption tails around 635–650 nm.

Various photopolymer systems have also been developed for analog as well as digital holographic memories and photoresists (see Refs. [7, 8] for details).

7.3 Reversible Memory Media

As described above, write-once optical disks (CD-R and DVD-R) using organic molecular materials are now commercially available. The next target is to develop erasable memory media. At present inorganic materials, such as magneto-optic or

Scheme 3.

Cyanine Dyes

Phthalocyanine Dyes

Metal Chelates of Azo Dyes

Figure 1.

phase-change materials, are used as the erasable media. These media are driven by a heat-mode optical recording method. Photon energy of the laser light is converted to heat energy on the recording media and used for recording. The memory density of the heat-mode recording is restricted by the diffraction limit of the laser light. Therefore, it is impossible in principle to increase the area memory density further. One possible way to overcome the limit is to explore photon-mode recording, which fully utilizes the versatile functions of light, such as wavelength (frequency), phase, polarity, and so on [9]. One of the candidates for photon-mode erasable media is photochromic molecules.

Photochromic molecules which can be used as the erasable memory media are required to have following properties.

- 1) archival storage capability (thermal stability of both isomers);
- 2) low fatigue (can be cycled many times without loss of performance);
- 3) high sensitivity and rapid response;
- 4) nondestructive reactivity.

Among these requirements, the most important are the thermal stability of both isomers and fatigue resistance. Although so many photochromic molecules have been reported, molecules which undergo thermally irreversible photochromic reactions are limited. Table 2 shows some typical photochromic molecules and their reactions. Thermally reversible photochromic molecules, such as azobenzene, spirobenzopyran, naphthopyran, thioindigo, anthracene dimer, dihydroazulene, and dihydroindolizine, cannot be used as the memory media. Although several attempts have been carried out to stabilize such unstable photochromic molecules by dispersing them in high- T_g polymer matrices [10], the stability is not sufficient for practical applications. Aggregate formation is another approach to stabilizing the photogenerated isomers [11], but the reversibility of the system is poor. So far, thermally irreversible molecules are limited to diarylethenes with heterocyclic aryl groups, furyl fulgides, naphthacenequinone, and sterically overcrowded stilbene derivatives. The photochromic properties of these molecules and their application to memory media will be described below.

7.3.1 Diarylethenes

cis-Stilbene is known to undergo a reversible photocyclization reaction to produce dihydrophenanthrene in the absence of oxygen. In the presence of air, however, the dihydrophenanthrene is irreversibly converted to phenanthrene by hydrogen elimination with oxygen (Eq. (1)).

Table 2. Photochromic molecules.

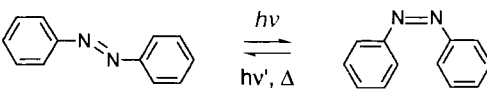

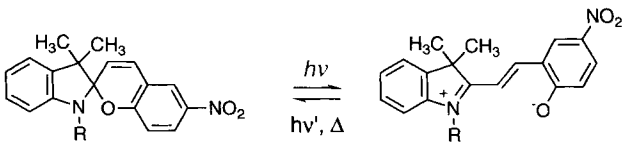

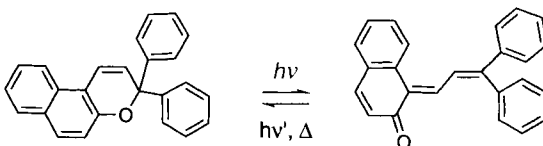

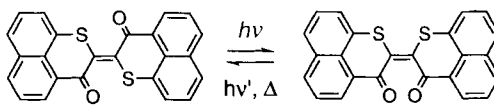

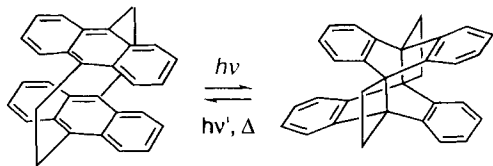

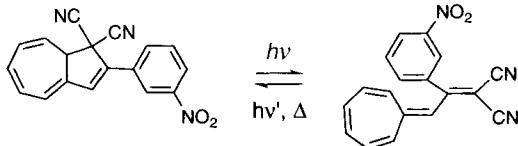

Name	Reaction

Stilbene derivative	

When methyl groups were substituted at the 2- and 6-positions of the phenyl rings, the molecule underwent a reversible photocyclization reaction, even in the presence of oxygen [12]. The lifetime of the dihydro-type yellow closed-ring isomer was, however, very short and it quickly returned to the colorless open-ring isomer. When the phenyl groups were replaced with heterocyclic five-membered rings, as in bis(2,5-dimethylthiophen-3-yl)perfluorocyclopentene **1a**, the closed-ring isomer **1b** became thermally stable and never returned to the open-ring isomer, even at 100 °C. The red closed-ring isomer **1b**, however, returned to the colorless open-ring isomer

Thermally Stable Compounds

Thermally Unstable Compounds

Figure 2. Thermally stable and unstable diarylethenes. The lifetimes of the closed-ring isomers of the thermally stable diarylethenes were longer than 12 h at 80 °C.

by irradiation with visible light (Eq. (2)). The diarylethenes with thiophene aryl groups underwent thermally irreversible photochromic reactions [13].

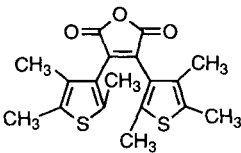

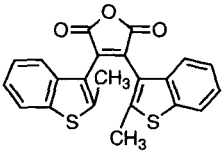

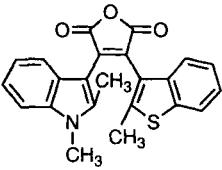

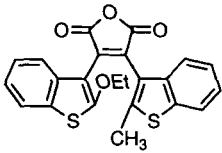

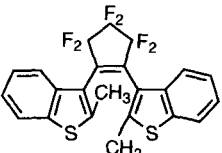

The stability was dependent on the type of aryl group, as shown in Figure 2. When the aryl groups were furan or thiophene rings, which have low aromatic stabilization energies, the closed-ring isomers were thermally stable and did not return to the open-ring isomers in the dark. On the other hand, photogenerated closed-ring isomers of diarylethenes with phenyl or indole rings, which have rather high aromatic stabilization energies, were thermally unstable. The photogenerated yellow color of the closed-ring isomer of 2,3-dimesitylbutene **9b** disappeared with a

half-life of 1.5 min at 20 °C. It returned quickly to the open-ring isomer. The closed-ring isomers of diarylethenes with indole rings, **7b** and **8b**, exhibited thermally reversible reactions. The different thermal stability behavior between diarylethenes with furan or thiophene rings and those with phenyl or indole rings agrees well with the theoretical prediction that the thermal stability depends on the aromatic stabilization energies of the aryl groups [14].

Diarylethenes undergo fatigue-resistant photochromic reactions [13]. Table 3 shows the fatigue-resistant properties of various diarylethenes. Benzene solutions

Table 3. Fatigue-resistant properties of diarylethenes in benzene.

Compound	Repeatable cycle number ^a	
	in air	under vacuum
	70	480
	3.7×10^3	1.0×10^4
	—	$>1.1 \times 10^4$
	$>1.0 \times 10^4$	—
	$>1.3 \times 10^4$	—

^a the number of repeatable cycles by which the absorbance of the closed-ring (or open-ring) isomer had decreased to 80 % of that in the first cycle.

containing diarylethenes (ca. 10^{-4} mol L $^{-1}$) were irradiated with shorter-wavelength light until the absorption intensity of the colored isomers reached 90 % of the photostationary state, then the colored isomers were completely bleached by irradiation with longer-wavelength light. This operation was repeated many times. Although diarylmaleic anhydride with thiophene rings cannot repeat the photochromic cycle more than 70 times in the presence of air, bis(2-methyl-1-benzothiophen-3-yl)-perfluorocyclopentene can repeat the cycles more than 1.3×10^4 times. Benzothiophene has much lower reactivity to singlet oxygen, which decomposes diarylethenes, and does not undergo a rearrangement reaction to produce by-products (see below). Diarylethenes with benzothiophene aryl groups undergo thermally irreversible and fatigue-resistant photochromic reactions [13].

It is worthwhile to note the difference in fatigue resistance of compounds **10** and **11** (Eqs. (3) and (4)) [15].

Compound **10a** has methyl groups at the 4- and 4'-positions of the thiophene rings, whereas compound **11a** has no methyl groups at these positions. Figure 3 shows the cycle number dependence of the absorbance of the bleached samples. The absorbance of **10a** remained almost constant even after 850 cycles, while the absorbance of **11a** gradually declined. At the same time a photostable violet product with an absorption maximum at 547 nm was formed. The molecular structure of the by-product is shown in Figure 4. Such by-product formation is the main fatigue process of dithienylethenes which have no methyl groups at the 4- and 4'-positions of the thiophene rings, in the absence of oxygen. The methyl substituents at the 4- and 4'-positions play an important role in improving the fatigue resistance of dithienylethenes.

Most diarylethenes show very large spectral shifts upon photoisomerization from the open- to the closed-ring isomers (>6600 cm $^{-1}$). These shifts are due to π -electron delocalization throughout the two condensed aryl rings. It is interesting to compare the spectral shift among dithienylethenes in which the substitution position of the thiophene rings on the ethene moiety is different, as shown in Eq. (5) [16].

Figure 3. Fatigue resistance of **10** and **11** in deaerated hexane solution. Absorbances of **10a** (●) and **11a** (■) were plotted after irradiation with visible light. The visible absorbance at 547 nm (□), which remained after visible irradiation of a hexane solution containing **11**, was also plotted.

Figure 4. ORTEP view of the by-product from **11a** and its chemical structure.

Photoirradiation of a hexane solution of **13a** with 366 nm light led to a decrease in the absorption at 336 nm and formation of a yellow solution, in which a new band appeared at 425 nm. The absorption maximum is blue-shifted as much as 109 nm in comparison with the maximum of **1b** (see Eq. (2)), in which thiophene rings are attached to the ethene moiety at the 3-positions. The open-ring isomer **13a**, on the other hand, gave an absorption band longer than that of **1a**. The red shift indicates that π -conjugation in the open-ring isomer extends further in the molecule. On the other hand, in **1a** π -conjugation is localized in each thiophene ring. By changing the substitution positions it is possible to control the extent of π -conjugation or the color of the open- and the closed-ring isomers. The diarylethenes so far synthesized cover all colors in the visible region from yellow to blue-green [13].

Practical optical memory media should have nondestructive readout capability. Photochromic reactions, in general, proceed in proportion to the number of photons absorbed by the compounds. Such linear-response characteristics cannot be used as the basis of memory media, because recorded memories are destroyed after many readout operations. There are two approaches to avoid such inconvenience: one is to introduce gated photochromic reactivity to the molecules, and another is to read the recorded memories by using light whose energy cannot induce photochromic reactions. The former approach will be described in this section. The latter approach will be discussed in Section 7.4.

A diarylethene with heterocyclic aryl groups has two conformations with the two rings in mirror and C_2 symmetries, and the cyclization reaction can proceed only from the C_2 symmetry, as shown in Figure 5. The photocyclization is prohibited when the compound is fixed in the mirror symmetry conformation. This means that compounds having special substituents which reversibly fix the conformation undergo gated photochromic reactions (Scheme 4) [17, 18].

The photochromic reaction of **14a** was completely prohibited in cyclohexane because the molecule is fixed in photoinactive mirror symmetry, or parallel conformation, by the intramolecular hydrogen bonding. The addition of a very small amount of ethanol to the cyclohexane solution gained the photochromic reactivity. The addition of ethanol converts the conformation into a photoactive anti-parallel conformation. Ethanol acts as a switch which controls the reactivity of the diarylethene molecule.

The hydrogen bonds can also be broken upon heating. In decalin the photocyclization did not occur below 60°C, but it was clearly observed above 100°C. This molecule has both chemical- and thermal-gated reactivity.

Figure 5. Conformations and photoreactivities of diarylethenes.

Scheme 4.

The diarylethenes **15**–**17** with oligothiophene aryl groups showed a thermal-gated reactivity (Eq. (6)) [19].

The cycloreversion quantum yield of **17b** ($\Phi = 0.00013$) was much lower than that of **15b** ($\Phi = 0.075$). The very low cycloreversion quantum yield was found to increase steeply as much as 34-fold when the temperature was raised from 25 to 150 °C. The large temperature dependence provides **17** with thermal-gated reactivity. The recorded memory in this system can be read many times with a weak laser, which does not raise the temperature of the medium. The memory can be erased with a high-intensity laser, which can raise the temperature of the medium to as high as 100–150 °C.

Dual-mode switching systems, which combine two reversible processes that can be addressed by two independent stimuli, can be used for nondestructive readout. Such a molecule, **18**, having photochromic and electrochromic active units has been synthesized [20, 21]. Upon irradiation with 312 nm light an acetonitrile solution containing **18a** turned deep blue, for which absorption maxima were observed at 590 and 340 nm. The absorption was due to the closed-ring isomer **18b** (Scheme 5). The conversion was over 98 %. The blue color disappeared upon irradiation with >600 nm light. The electrochemical activity of the two isomers, **18a** and **18b**, was examined in acetonitrile. Whereas the open-ring isomer was electrochemically inert within the –1 to +1 V domain, the closed-ring isomer, which is an extended hydroquinone, presented a reversible oxidation wave at +735 mV (with respect to SCE) corresponding to the formation of quinonoid form **19**. The quinonoid form **19** was photochemically inactive. Irradiation of the acetonitrile solution of **19** with >600 nm light for 8 h resulted in less than a 2 % decrease in the absorbance at the maximum. Thus, in the reduced hydroquinone form **18b** the system is photochromic, while oxidation to the quinonoid form **19** can be used to effectively block the photochemical coloration. Such multi-mode switching was also observed in a photochromic mixture system [22].

7.3.2 Furyl Fulgide Derivatives

Furyl fulgide **20** (Eq. (7)) is the first known example of thermally irreversible photochromic molecules. Although phenyl fulgides such as **21** have been known to show photochromic reactions, photogenerated dihydronaphthalene derivatives such as **21C** (Eq. (8)) are thermally unstable and undergo irreversible side reactions, i.e., 1,5-hydrogen shifts to produce 1,2-dihydronaphthalene derivatives [23–26]. This

Scheme 5.

undesirable performance was much improved by replacing the phenyl group with a furyl group [27]. Compound **20E** underwent a thermally irreversible photocyclization reaction to produce the closed-ring isomer **20C** quantitatively (Eq. (7)). The rather low cycloreversion quantum yield and the weak absorption band of **20C** in the UV region ($\sim 366 \text{ nm}$) yielded high conversion from the open- to the closed-ring isomer.

The thermal irreversibility of the closed-ring isomer was ascribed to the steric hindrance of the methyl groups at the reactive center; these methyl groups were said to prevent the disrotatory thermal cycloreversion reaction [27, 28]. This is not the case. The thermal stability of the closed-ring isomer of the furyl fulgide is due to the low aromatic stabilization energy of the furyl group, as evidenced in the case of diarylethenes with heterocyclic aryl groups [14]. Because of the low aromatic stabilization energy the ground-state energy difference between the open- and closed-ring isomers becomes small, and this stabilizes the closed-ring isomer.

One of the serious defects of the furyl fulgide is low fatigue resistance. Tomoda and co-workers prepared fulgide derivatives with various types of heterocyclic aryl groups and compared the thermal stability of the colored closed-ring isomers in poly(methyl methacrylate) (PMMA) film and the fatigue resistance [29, 30]. The results are shown in Figures 6 and 7, from which it can be seen that the colored closed-ring isomer of furyl fulgide is not stable. The absorbance of **20C** disappeared after one-day storage in PMMA film at 80 °C. The disappearance is not due to cycloreversion but to decomposition. Furthermore, the coloration/decoloration cycles are limited to fewer than 50 in toluene in the presence of oxygen. Feryl fulgide itself is not fatigue-resistant.

The fatigue resistance was improved when the furyl group was replaced with indole or oxazole [29, 30]. The coloration/decoloration cycles of oxazolyl fulgide **26** could be repeated more than 500 times in toluene, even in the presence of oxygen. The fatigue resistance strongly depends on the aryl groups.

Another defect of fulgide derivatives is solvolysis. The maleic anhydride structure is destroyed in alcohols or protic solvents. To avoid such solvolysis the maleic anhydride structures were changed to maleimides; the maleimide derivatives were stable in alcohol solutions.

Upon UV irradiation the furyl fulgide undergoes not only cyclization but also an *E*–*Z* photoisomerization reaction (Scheme 6). The ratio between the cyclization and the *E*–*Z* isomerization depends on the steric hindrance of substituent R¹. Feryl fulgide derivatives with various R¹ substituents were prepared and the quantum yields were compared [31–34]. The results are summarized in Table 4.

When R¹ was changed from methyl to *n*-propyl, the *E*–*Z* isomerization quantum yield decreased from 0.13 to 0.04. It became almost zero when bulky substituents, such as isopropyl or *t*-butyl, were introduced. At the same time the cyclization quantum yield (Φ_{EC}) increased. The cyclization quantum yield of **31** is four times larger than that of **20**. Introduction of bulky substituents is effective in increasing the coloration quantum yield.

Figure 6. Thermal stability at 80°C of the closed-ring isomers of fulgide derivatives (15–20 wt. % in PMMA film).

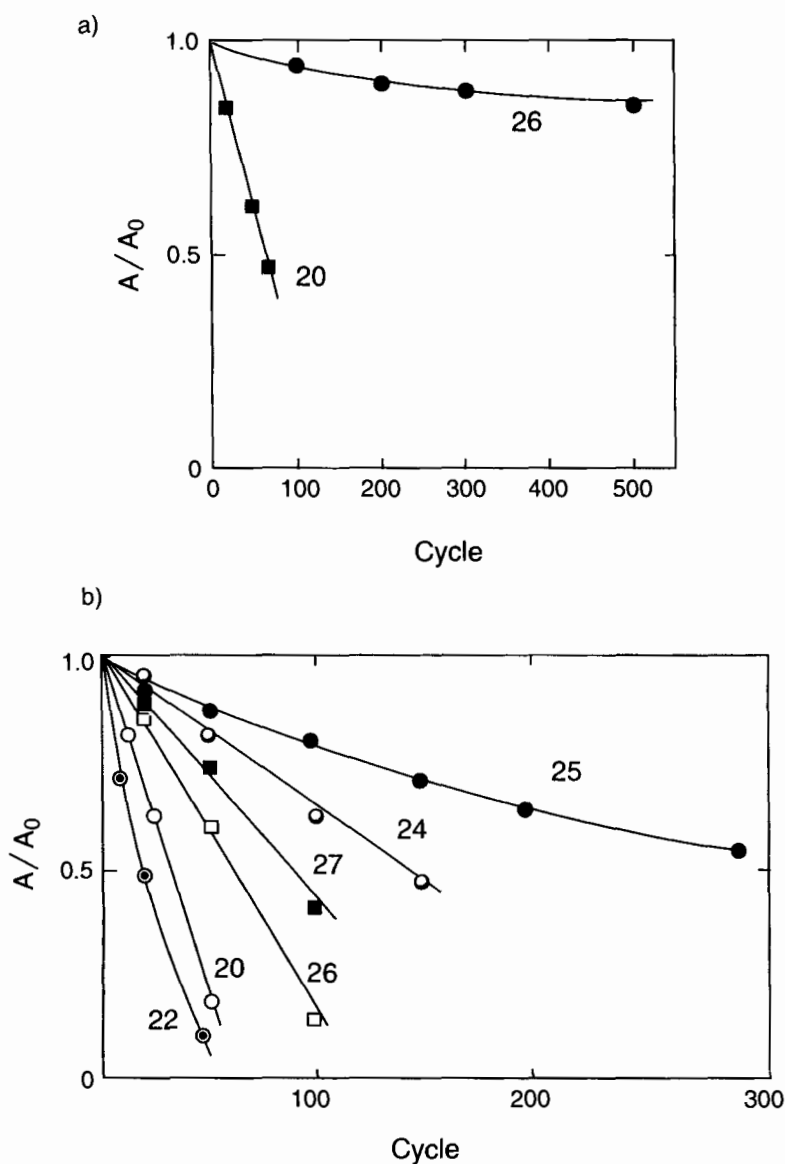

Figure 7. Fatigue resistance of fulgide derivatives a) in toluene and b) in PMMA film. A_0 and A were the absorbances of the first cycle and after n coloration/decoloration cycles, respectively.

Replacement of isopropylidene groups with bulky norbornylidene or adamantylidene groups was carried out with the aim of increasing the cycloreversion quantum yield [32, 35, 36]. Although norbornylidene groups were not effective, adamantylidene groups dramatically increased the yield. Finally, both isopropyl and adamantylidene groups were introduced into the fulgide molecular structure.

NBO : 7- norbornylidene

ADO : 2 - adamantylidene

Scheme 6.

Table 4. Quantum yields of furyl fulgide derivatives in toluene.

Compound	Φ_{EC}	Φ_{EZ}	Φ_{ZE}	Φ_{CE}
20	0.18	0.13	0.11	0.048
28 ^a	0.34	0.06	0.12	0.027
29 ^a	0.45	0.04	0.10	0.044
30 ^a	0.62	0.00	0.06	0.040
31 ^a	0.79	0.00	—	0.034
32	0.20	0.30	0.42	0.057
33	0.12	0.10	0.10	0.21
34	0.51	0.02	0.05	0.26

^ain chloroform.

The cyclization and cycloreversion quantum yields of **34** were increased to 0.51 and 0.26, respectively. Both yields of **34** were reasonably high.

Indolyl fulgide, having a dimethylamino substituent at the 5-position of the indole ring **35**, undergoes an acid-gated photochromic reaction as shown in Scheme 7 [37]. In the absence of acid, the open-ring isomer **35E** converts to the closed-ring isomer **35C**, but the reverse process is strongly suppressed. The quantum yield is less than

Scheme 7. Acid-gated photochromic reactions of an indolyl fulgide **35** with a dimethylamino substituent.

10^{-4} . Upon addition of an acid, such as trichloroacetic acid, the absorption maximum showed the hypsochromic shift and the cycloreversion quantum yield increased as much as 10^3 -fold. Protonation to the dimethylamino group decreased the electron-donating ability of the substituent and resulted in the change in reactivity. This acid-gated reactivity is potentially applicable to nondestructive readout in a polymer memory medium.

7.3.3 Phenoxynaphthacene Quinones

Another class of thermally irreversible photochromic molecules comprises phenoxynaphthacene quinone derivatives (**36–40**). The photogenerated orange isomer (*ana* form) never returns to the colorless isomer (*trans* form) at ambient temperature. Although the derivative in which R is hydrogen only slightly shows photochromic reactivity, all derivatives having amino or alkyl substituents in the *para* position of the phenoxy group undergo normal photochromism.

The *trans*-to-*ana* and the reverse quantum yields of **40** were determined to be 0.60 and 0.10, respectively. The coloration/decoloration cycle could be repeated more than 500 times. The quantum yield of side product formation was also determined to be 5×10^{-4} , which agrees with the fatigue resistance of this molecule [41]. Vari-

36: $R = -NH_2$ 37: $R = -CH_2COOH$ 38: $R = -CH_2CH \begin{matrix} \nearrow COOCH_3 \\ \searrow NH_2 \end{matrix}$ 39: $R = -CH_2CH \begin{matrix} \nearrow COOC_4H_9 \\ \searrow NH_2 \end{matrix}$ 40: $R = -CH_2CH \begin{matrix} \nearrow COOC_4H_9 \\ \searrow NHCOOC(CH_3)_3 \end{matrix}$

ous types of polymers containing the chromophores were prepared and their photochromic performance was also examined [39, 40].

7.3.4 Stilbene Derivatives

Stilbene derivatives also undergo thermally irreversible photochromic reactions. Among the derivatives, the thioxanthenes **41** and **42** are of the most interest from the viewpoint of their application to memory media [42–44].

41 : $X = CH_2$, $R^1 = CH_3$, $R^2 = OCH_3$, $R^3 = H$ 42 : $X = S$, $R^1 = H$, $R^2 = NO_2$, $R^3 = N(CH_3)_2$

Major advantages of **41** and **42** over other photochromic systems are:

- 1) the photoswitching between **P** and **M** isomers can be detected by more discriminative detection techniques, such as circular dichroism (CD) or optical rotation dispersion (ORD) spectra, which change the sign between the isomers; and
- 2) the recorded memory can be read out without affecting the ratio of the two isomers by using ORD and employing a wavelength outside the absorption region.

Irradiation of hexane solutions of **P-42** at 365 and 435 nm resulted in two distinct photostationary states. Upon irradiation with 365 nm light the photostationary state was composed of 70 % **M-42** and 30 % **P-42**, whereas the photostationary

Figure 8. CD spectra of **M-42** (negative) and **P-42** (positive), and the photostationary states generated by irradiation at 365 and 435 nm in hexane.

state with 435 nm light was composed of 10 % **M-42** and 90 % **P-42**. The interconversion between **M-42** and **P-42** was reversible and any racemization was not observed after 60 cycles. Figure 8 shows the CD spectra of the two photostationary states. The CD spectra changed the sign by alternate irradiation with 365 and 435 nm light. The change in ORD spectra can be detected in principle by using visible light of wavelength longer than 500 nm, which does not induce the photochromic reaction. The two states could also be detected by the fluorescence intensity change [44]. One serious defect of this system is that the photochemical reactivity is strongly suppressed in rigid solid matrices.

The photochemical interconversion between two states, **P-42** and **M-42**, was prohibited by the addition of trifluoroacetic acid [44]. The fluorescence was also quenched by the acid. The protonation of the dimethylamino group lost the effective donor–acceptor system and changed the photoreactivity.

The sterically overcrowded stilbene derivatives were also useful dopants which caused photoinduced transition between induced cholesteric and nematic phases of liquid crystals [45, 46]. By alternate irradiation with light of different wavelengths, or left or right circularly polarized light, the phase transitions were successfully induced.

7.4 Nondestructive Readout

Several methods using fluorescence or infrared absorption as readout signals have been proposed to avoid destructive readout. A diarylethene having dithieno(thiophene) units **43a** [47, 48] shows fluorescence in the open-ring isomer (Eq. (9)).

Figure 9 shows the absorption spectra of **43a** and **43b**. Irradiation of the main band of the open-ring isomer **43a** at 400–500 nm gave no reaction, while the cyclization reaction proceeded by irradiation at wavelengths less than 400 nm. The closed-ring isomer presented an intense broad absorption band at 704 nm. Cycloreversion

Figure 9. Absorption spectra of **43a** (···) and **43b** (—) in methanol.

occurred upon irradiation with >600 nm light. The open-ring isomer was found to present a strong emission at 589 nm when excited in the 400–500 nm region. In contrast, the closed-ring isomer displayed only a weak fluorescence. The large change in fluorescence intensity between the open- and closed-ring isomers makes it possible to use the change as the readout signal. When the fluorescence can be detected without influencing the ratio of the two isomers, the readout method becomes non-destructive. The absorption band at 459 nm of the open-ring isomer was photochemically inactive. The analogous band of the closed-ring isomer ($\lambda_{\text{max}} = 454$ nm) also had very low activity; a slow conversion of less than 10 % h^{-1} was observed. Therefore, the spectral change during fluorescence detection using a narrow range of exciting wavelengths was negligible. Although the system does not give a perfect performance of nondestructive readout, a very large number of fluorescence readings can in principle be performed before significant change takes place.

As described in Section 7.3.4, the recorded information can be read many times without destruction by light whose energy cannot cause any molecular change [49, 50]. Infrared light can be used to detect the difference between the open- and closed-ring isomers. The region of C=C stretching ($1400\text{--}1650\text{ cm}^{-1}$) is highly selective and suitable for detecting the difference. In the spectral region, the open-ring isomer **11a** has three bands at 1637, 1592, and 1544 cm^{-1} . The first one is due to the C=C bond of perfluorocyclopentene, and the others can be ascribed to the double bonds of the thiophene rings. In the closed-ring forms three new bands appeared at 1612, 1574, and 1503 cm^{-1} , which are assigned to the C=C bonds of the newly generated conjugated system. It is possible to detect the difference in the isomers using infrared spectra. Conceptually it is proposed to construct an optical memory system in which the information is written and erased by UV and visible photons that activate the photochromic process; the reading is achieved by infrared photons unable to cause any molecular rearrangement.

7.5 Near-field Memory

Various approaches have been proposed to increase the memory density: decreasing the spot diameter by use of short-wavelength lasers [51], three-dimensional recording [52, 53], and multi-wavelength recording [54]. One of the approaches to the ultra-high-density optical memory is near-field optical recording [55, 56]. The recording density in conventional optical recording is limited by the diffraction limit of light and the numerical aperture of the lens. Therefore, efforts have been focused on developing shorter-wavelength lasers [51]. In near-field recording, in contrast, the size of the recording mark depends only on the diameter of the probe tip aperture. Therefore, the recording density can be increased at will, in principle, if a small aperture tip is available. Photochromic media are suitable for near-field recording because of their ultra-high resolution and writing speed.

Amorphous thin recording medium (300 nm) was prepared by vacuum evaporation of dithienylethene **10a** on a glass substrate and used for the near-field optical

recording. The film was first colored by irradiation with UV light ($300\text{ nm} < \lambda < 400\text{ nm}$) and then bleached with 529 nm light from a small probe tip. The diameter of the mark was as small as $\sim 100\text{ nm}$. The mark could be erased by irradiation with UV light. The result represents a 60-fold improvement in recording density compared with current conventional MO and PC recording systems.

7.6 Conclusions

When we intend to apply organic molecular materials, especially photochromic dyes, to optical memory media, the indispensable condition is stability, both thermal and photochemical. The photogenerated isomers are required never to return to the initial isomers in the dark, even at elevated temperatures, e.g., 80°C . In addition, the coloration/decoloration can be cycled many times while the photochromic performance is maintained, and the memory media are provided with nondestructive readout capability. Although several molecules which fulfill the former condition have been developed, some problems still remain to gain access to molecules and systems which fully satisfy the latter condition.

At present the most robust photochromic molecules are diarylethenes with benzothiophene aryl groups [13]. They undergo more than 1.3×10^4 photochromic cycles in the presence of oxygen without destruction. Recently crystalline photochromic diarylethenes have been developed [57, 58] which could repeat the cycles more than 10^5 times.

Although several attempts to develop gated photochromic systems have been made to avoid destructive readout as described in Section 7.3, their functions are not adequate for practical application. Recently a new practical technology to avoid destructive readout has been developed [53], using a reflection confocal microscope as a readout system. The wavelength of the readout laser light is longer than the absorption edge of the colored isomer. The method was successfully applied to nondestructive readout of data stored in three-dimensional photochromic memory. We are now close to the goal of constructing an erasable optical memory system using organic molecular materials.

8 Nonlinear Optics

*Stephan Houbrechts, Eric Hendrickx, Thierry Verbiest, Koen Clays, and
André Persoons*

Nonlinear optics is a rapidly evolving field that studies the interaction of strong electric fields (e.g., high-intensity light) with matter. Historically, it had to await the advent of laser sources (high-intensity radiation sources) before most of the small optical nonlinearities could be addressed [1, 2]. Though, since its genesis the field has been continuously expanding. For several decades now, nonlinear optics has been recognized for its applications in the domain of opto-electronics and photonics [3, 4]. High-performance electro-optical switches for telecommunications and optical information processing are all based on materials with high nonlinear optical (NLO) properties. In addition, NLO materials also found their use as eye or photo-sensor protection materials due to their light-intensity-dependent transmission properties [5]. This chapter is intended as an introduction to nonlinear optics. Emphasis is on organic structures that exhibit second-order NLO properties, on various strategies to enhance the molecular nonlinearities, and on the methods used to determine them. More extensive discussions of the work performed in this field can be found in the literature [3–9].

8.1 Introduction to Nonlinear Optics

8.1.1 The Basics of Nonlinear Optics

The interaction of light with a molecule can be described by the influence of its electric field on the electron density. The electric field E acting on the molecule (or material) induces a distortion of the electron density, with (induced) dipole moment μ_{ind} (or polarization P on the macroscopic level). For weak electric fields the magnitude of this induced moment (polarization) can be expected to be linear with the amplitude of the electric field. This linear proportionality suffices to explain the linear optical properties, e.g., refraction and optical activity. Yet, when the electric

field strength approaches that of the internal electric field within the molecule, the linear relationship no longer holds and nonlinear terms have to be taken into account. In these circumstances, the induced dipole moment (induced polarization) can be expressed in terms of a power series (Eqs. (1) and (2)).

$$\mu_{\text{ind}} = \alpha E + \beta EE + \gamma EEE + \dots \quad (1)$$

$$P_{\text{ind}} = \chi^{(1)} E + \chi^{(2)} EE + \chi^{(3)} EEE + \dots \quad (2)$$

The molecular constants α , β , and γ are called the linear polarizability, the quadratic (or first) hyperpolarizability, and the cubic (or second) hyperpolarizability respectively. The related macroscopic quantities $\chi^{(n)}$ defined by Eq. (2) denote respectively the first-, second-, and third-order susceptibility. Although the precise relationship between $\mu_{\text{ind}}(P_{\text{ind}})$ and E is tensorial by nature, it is sufficient for the present section to use the scalar notation. The quadratic terms β and $\chi^{(2)}$ are responsible for second-order NLO effects such as the linear electro-optic or Pockels effect and frequency doubling (or second-harmonic generation, SHG). In like manner do the cubic terms γ and $\chi^{(3)}$ account for third-order NLO properties such as the Kerr effect and third harmonic generation (THG). Nevertheless, as the nonlinear terms βEE and γEEE in general are much smaller than αE , NLO effects were seldom observed before lasers were at hand. Utilizing the correct trigonometric relations, the appearance of SHG and THG can easily be verified by expressing the electric field of a light wave as $E = E_0 \cos(\omega t)$.

$$\begin{aligned} \mu_{\text{ind}} &= \alpha E_0 \cos(\omega t) + \beta (E_0 \cos(\omega t))^2 + \gamma (E_0 \cos(\omega t))^3 + \dots \\ &= \frac{\beta E_0^2}{2} + \left(\alpha + \frac{3\gamma E_0^2}{4} \right) E_0 \cos(\omega t) + \frac{\beta E_0^2}{2} \cos(2\omega t) + \frac{\gamma E_0^3}{4} \cos(3\omega t) + \dots \end{aligned} \quad (3)$$

Apart from SHG and THG, Eq. (3) also reveals a second-order DC contribution (optical rectification) and the optical Kerr effect (i.e., the dependence of the term at the original frequency upon the light intensity $I \propto E_0^2$). A similar expression can be derived for the macroscopic polarization. Other NLO effects can be described utilizing different frequencies and/or static $E(0)$ or magnetic $B(0)$ fields (see Table 1).

In the literature however, other related parameters, besides $\chi^{(2)}$, are often used to describe the macroscopic second-order NLO properties of materials. The SHG nonlinear coefficient d and the linear electro-optic coefficient r are the parameters commonly used for second-harmonic generation and the Pockels effect respectively [3, 5]. They are related to $\chi^{(2)}$ according to Eqs. (4) and (5).

$$d = \frac{\chi^{(2)}}{2} \quad (4)$$

$$r = -\frac{8\pi\chi^{(2)}}{n_0^4} \quad (5)$$

Table 1. Certain NLO contributions to the induced dipole moment.

Dipole moment contribution	NLO effect
$\mu(0) \propto \beta E(\omega)E(\omega)$	optical rectification
$\mu(\omega) \propto \beta E(0)E(\omega)$	Pockels effect
$\gamma E(0)E(0)E(\omega)$	DC Kerr effect
$\gamma E(\omega)E(\omega)E(\omega)$	optical Kerr effect
$\mu(2\omega) \propto \beta E(\omega)E(\omega)$	SHG
$\gamma E(0)E(\omega)E(\omega)$	electric-field induced SHG
$\gamma B(0)E(\omega)E(\omega)$	magnetic-field induced SHG
$\mu(\omega_1 \pm \omega_2) \propto \beta E(\omega_1)E(\omega_2)$	frequency mixing
$\mu(3\omega) \propto \gamma E(\omega)E(\omega)E(\omega)$	THG

8.1.2 Symmetry Restrictions

The anisotropy of molecules and matter imposes that the proportionality factors (Eqs. (2) and (3)) are tensorial quantities (vide supra). As such, the relations between the dipole moment vector and the electric field vector can be defined by Eq. (6),

$$\begin{aligned}\mu_i &= \sum_j \alpha_{ij} E_j + \sum_{j,k} \beta_{ijk} E_j E_k + \sum_{j,k,l} \gamma_{ijkl} E_j E_k E_l \\ &= \alpha_{ij} E_j + \beta_{ijk} E_j E_k + \gamma_{ijkl} E_j E_k E_l\end{aligned}\quad (6)$$

where summation over the repeated indices is implied. Consequently, α is a second-rank tensor (or a 3×3 matrix), β a third-rank tensor ($3 \times 3 \times 3$ matrix), and γ a fourth-rank tensor ($3 \times 3 \times 3 \times 3$ matrix) with respectively 9, 27, and 81 tensor components. Fortunately, the number of independent tensor components is severely restricted by molecular symmetry (or the symmetry of the medium in case of the susceptibilities) as many components are equivalent or equal to zero. As an example, let us consider the quadratic hyperpolarizability, and a particular physical situation (molecule, electric fields, and induced moments are fixed in space) described by Eq. (6). This situation can now also be described in an alternative coordination frame. Like the vectors, the new β'_{lmn} and old β_{ijk} tensor components of the first hyperpolarizability relate to each other through a transformation matrix t .

$$\begin{aligned}\mu'_l &= t_{li} \mu_i \\ E'_m &= t_{mj} E_j \\ \beta'_{lmn} &= t_{li} t_{mj} t_{nk} \beta_{ijk}\end{aligned}\quad (7)$$

If we consider t to be a symmetry operation T , than all properties are described identically in both frames. As each symmetry operation produces an expression like Eq. (8), the number of independent tensor components is restricted.

$$\beta_{lmn} = T_{li} T_{mj} T_{nk} \beta_{ijk}\quad (8)$$

Note that the inversion transformation $T_{li} = -\delta_{li}$ yields $\beta_{lmn} = -\beta_{lmn}$ and thus $\beta_{lmn} = 0$. As a consequence, no second-order, or more general even-order, NLO effects can be present for molecules that are centrosymmetric. Moreover, the absence of an inversion center is required for the macroscopic symmetry of the medium [3, 5].

For certain macroscopic nonlinear parameters the tensor notation can be simplified due to the intrinsic symmetry of the experiment, e.g., second-harmonic generation and the linear electro-optic effect. Let us first consider SHG. The second-order contribution to the polarization is given by Eq. (9).

$$P_i^{(2)} = \chi_{ijk}^{(2)} E_j(\omega) E_k(\omega) \propto d_{ijk} E_j(\omega) E_k(\omega) \quad (9)$$

As $E_j(\omega)$ and $E_k(\omega)$ are indistinguishable (experimentally only one laser beam is used), the two last indices may be interchanged ($d_{ijk} = d_{ikj}$) and the third-rank tensor d_{ijk} can be represented as a two-dimensional matrix (Eq. (10)).

$$\begin{aligned} d_{ijj} &= d_{ij} \\ d_{i23} &= d_{i32} = d_{i4} \\ d_{i13} &= d_{i31} = d_{i5} \\ d_{i12} &= d_{i21} = d_{i6} \end{aligned} \quad (10)$$

In contrast to the SHG coefficient, the electro-optic coefficient r_{ijk} is symmetric in its first two indices for a lossless, not optically active, material. This follows from Eq. (11), which relates the electro-optical coefficient to the impermeability tensor η_{ij} (the matrix inverse of the dielectric permeability tensor ϵ_{ij}), a real and symmetric tensor under the stated conditions [3],

$$\eta_{ij} = \eta_{ij}^0 + r_{ijk} E_k + \cdots \quad (11)$$

with η_{ij}^0 the linear impermeability. As such the electro-optic coefficient can be contracted as in Eq. (12).

$$\begin{aligned} r_{iik} &= r_{ik} \\ r_{23k} &= r_{32k} = r_{4k} \\ r_{13k} &= r_{31k} = r_{5k} \\ r_{12k} &= r_{21k} = r_{6k} \end{aligned} \quad (12)$$

8.1.3 Systems of Units

The system of units most frequently employed in nonlinear optics is the Gaussian (or cgs) system. Sporadically, the SI unit system is used. It is important to be able to convert between the two systems. However, not only do the units need to be con-

Table 2. Some units and conversion factors in nonlinear optics.

Property		cgs ^a	SI	Conversion factor N^b
Dipole moment	μ	sC cm	C m	2.998×10^{11}
Polarization	P	sC cm ⁻²	C m ⁻²	2.998×10^5
Electric field	E	sV cm ⁻¹	V m ⁻¹	3.334×10^{-5}
Linear polarizability	α	cm ³	C m ² V ⁻¹	$(2.998)^2 \times 10^{15}$
1st hyperpolarizability	β	cm ⁵ sC ⁻¹ (esu)	C m ³ V ⁻²	$(2.998)^3 \times 10^{19}$
2nd hyperpolarizability	γ	cm ⁷ sC ⁻² (esu)	C m ⁴ V ⁻³	$(2.998)^4 \times 10^{23}$
Linear susceptibility	$\chi^{(1)}$	dimensionless	C m ⁻¹ V ⁻¹	$(2.998)^2 \times 10^9$
2nd-order susceptibility	$\chi^{(2)}$	cm sV ⁻¹	C V ⁻²	$(2.998)^3 \times 10^{13}$
3rd-order susceptibility	$\chi^{(3)}$	cm ² sV ⁻²	C m V ⁻³	$(2.998)^4 \times 10^{17}$

^a 1 C = 2.998×10^9 sC, 299.8 V = 1 sV, ^b SI $\times N$ = cgs.

verted correctly, but the quantities need to be treated according to their different definitions in different systems as well. Table 2 lists the conversion factors for the quantities of importance in second- and third-order nonlinear optics.

Note that for the macroscopic nonlinear parameters ($\chi^{(2)}$, d and r) the MKS system is frequently used ($1 \text{ pm V}^{-1} = 3.387 \times 10^{-9} \text{ esu}$).

8.2 Measurement Techniques

8.2.1 Electric-field-induced Second-harmonic Generation (EFISHG)

For the experimental determination of the second-order first hyperpolarizability, some sort of non-centrosymmetry has to be present in the solution. This can be achieved by applying a static electric field over a solution of neutral molecules with dipolar chromophores. Implicitly, this description limits the applicability of this Electric-field-induced second-harmonic generation (EFISHG) technique:

- 1) No ionic species can be measured: they would migrate rather than orient under the influence of the static field.
- 2) Only dipolar molecules can be measured, because reorientation in the electric field is necessary to induce the non-centrosymmetry.

The latter limitation did not prove a disadvantage until recently. The paradigm of second-order nonlinear optics used to be an asymmetrically *para*-substituted (azo)-benzene or stilbene, and hence a dipolar molecule.

EFISHG [10–12] is inherently a third-order process: two optical fields are necessary to generate the optical harmonic, but a third (static) field is also present. A complete analysis of the different contributions to the second-order signal obtained

from EFISHG reveals that there are different contributions to the molecular third-order nonlinear optical polarizability which are inherently determined by the third-order process. There is a purely electronic third-order contribution, inherently third-order; a purely vibrational contribution, also third-order in nature; and a so-called average dipolar rotational contribution, γ_r . The latter contribution is in fact a combination of a second-order parameter with another field, yielding a third-order contribution. For the analysis toward a value for the second-order nonlinear polarizability β of dipolar molecules, we have to focus on this contribution. The experimental conditions are parallel polarizations of fundamental, second harmonic, and static field.

The rotational contribution stems from the second harmonic that is generated by partially oriented dipolar molecules. The orientation is induced by the lowering of the energy when a dipole moment orients parallel to the field. The orientation of the molecules induces a specific phase relation that leads to the generation of a coherent second-harmonic signal. The coherence length of the solution and the interaction length, i.e., the length of the cell containing the solution, ultimately determine the magnitude of this coherent signal. The wedge-shaped cell is therefore instrumental to factor out this length dependence and to accurately determine the amplitude. Referencing can be done in different ways. Either quartz can be used, with the appropriate $\chi^{(2)}$ value, or a solution of known concentration of a dipolar chromophore with known first hyperpolarizability value can be used.

The important question in EFISHG, especially in the light of the complementarity with hyper-Rayleigh scattering (HRS), is: What is actually experimentally determined? The expression for the rotational contribution is determined by the scalar product of the dipole moment vector with the vector part of the third-rank hyperpolarizability tensor (Eq. (13)).

$$\gamma_r = \frac{\mu \cdot \beta_{\text{vec}}}{5kT} \quad (13)$$

As will be explained in Section 8.3.3, the reduction spectrum of rank-three tensors contains, in the general case, one (pseudo)scalar, three vectors, two (pseudo)deviators, and one septor [13]. Here, we only have to deal with the vectorial parts. They transform as a vector. Hence, the scalar product of the dipole moment vector with a vector part of the first hyperpolarizability tensor can be written as the simple product of two scalars, when we designate θ as the angle between the molecular axis (z -axis) and the dipole moment axis (Eq. (14)).

$$\gamma_r = \frac{\mu_z \beta_z \cos \theta}{5kT} \quad (14)$$

The assumption is often made that the two vectors are collinear, leading to the familiar expression, Eq. (15), for EFISHG.

$$\gamma_r = \frac{\mu_z \beta_z}{5kT} \quad (15)$$

From the measurement of the intensity of the generated second harmonic for a dipolar molecule and with knowledge of the value of the dipole moment, an experimental value for β can be obtained. The relation of this value to the hyperpolarizability tensor components, in the completely general case ($\beta_k = \frac{1}{3}(\beta_{kmn}\delta_{nm} + \beta_{nkm}\delta_{nm} + \beta_{nmk}\delta_{nm})$), is given by Eq. (16).

$$\beta_z = \beta_{zzz} + \frac{1}{3}(\beta_{zyy} + \beta_{zxx} + \beta_{yyz} + \beta_{xzx} + \beta_{yyz} + \beta_{xxz}) \quad (16)$$

In the more specific case of second-harmonic generation, with degeneracy between the optical fields ($\beta_{ijk} = \beta_{ikj}$), Eq. (16) reduces to Eq. (17).

$$\beta_z = \beta_{zzz} + \frac{1}{3}(\beta_{zyy} + \beta_{zxx} + 2\beta_{yyz} + 2\beta_{xzx}) \quad (17)$$

When Kleinman [14] symmetry is applicable (i.e., $\beta_{ijk} = \beta_{jik}$), Eq. (18) holds.

$$\beta_z = \beta_{zxx} + \beta_{zyy} + \beta_{zzz} \quad (18)$$

These relations between the experimental observable in EFISHG, β_z , and the molecular third-rank hyperpolarizability tensor components do not reflect the (approximate) symmetry of the molecule yet. When we accept (approximate) C_{2v} symmetry for a molecule with a planar conjugated π -electron system (in the xz -plane), we are still left with these three non-zero and independent tensor components.

For $C_{\infty v}$ symmetry, there are only two independent tensor components β_{zzz} ; $\beta_{zyy} = \beta_{zxx}$, resulting in Eq. (19).

$$\beta_z = \beta_{zxx} + \beta_{zzz} \quad (19)$$

In most cases, for charge transfer molecules, only a single major non-zero tensor component can be assumed. Then, Eq. (19) finally reduces to Eq. (20).

$$\beta_z = \beta_{zzz} \quad (20)$$

It is important to make the distinction, and state the exact relation, between the measured observable and the actual hyperpolarizability tensor component(s), even if, for specific experimental conditions and molecular symmetries, their values turn out to be identical. What is also important is the fact that only one experimental condition is favorable for EFISHG, namely parallel polarizations for all optical and static fields. This leads to only one observable, resulting in only a single value to be deduced. It is not possible with EFISHG to determine more than one tensor component; hence, one often contends either with the approximation that β_{zzz} was determined, or with the statement that β_z was obtained, in any of the above-mentioned relations to the individual tensor components. Even then, the assumption that the dipole moment vector and the vector part of the third-rank tensor along the molec-

ular z -axis are collinear, is implicitly made. However, even if one was to be interested in checking this assumption, it would not be possible, since EFISHG can only provide one independent observable.

8.2.2 Hyper-Rayleigh Scattering (HRS)

In hyper-Rayleigh scattering (HRS) [15–17], no extrinsic non-centrosymmetry is induced in a solution. Advantage is taken of the temporal and spatial deviation from the average centrosymmetry caused by fluctuations. Due to the isotropic distribution of chromophores in the solution without an orienting field, the relations between the experimental observable and the hyperpolarizability tensor components are determined by the averaging of direction cosines over all possible orientations. The results have been obtained for the general case, i.e., as a function of all 27 possible hyperpolarizability tensor components [18, 19]. Again, degeneracy of the optical fields in hyper-Rayleigh scattering ($\beta_{ijk} = \beta_{jik}$, dispersive HRS) [20] reduces this number to 18, while Kleinman symmetry ($\beta_{ijk} = \beta_{jik}$) results in only 10 independent components. Molecular symmetry then ultimately determines the number of non-zero components.

Since, in HRS, there is no preferred orientation induced by an additional static field, there is the possibility of varying the experimental conditions in order to increase the number of independent observables. The number of theoretically possible independent observations, and hence the number of tensor components that can be obtained by HRS, is at most five. For parametric light scattering, this number is six, due to the possibility of distinguishing between the two optical fundamental fields [20]. The experimental difficulty has precluded the determination of this number of components. What is experimentally realistic in HRS is an additional depolarization measurement, apart from the classical measurement of the intensity of the second-order incoherent scattered light. The two measurements, the total intensity measurement and the depolarization ratio (or two intensity measurements, one with parallel and one with perpendicular polarization for fundamental and second harmonic), represent two independent observables and allow the experimental determination of two tensor components. For molecules of C_{2v} symmetry, these are β_{zzz} and β_{zxx} , resulting for the total intensity measurement in Eqn. (21),

$$\langle \beta_{\text{HRS}}^2 \rangle = \frac{6}{35} \beta_{zzz}^2 + \frac{16}{105} \beta_{zzz} \beta_{zxx} + \frac{38}{105} \beta_{zxx}^2 \quad (21)$$

and for the depolarization ratio ρ , measured under 90° , in Eqn. (22).

$$\rho = \frac{15 + 18q + 27q^2}{3 - 2q + 11q^2} \quad \text{with } q = \frac{\beta_{zxx}}{\beta_{zzz}} \quad (22)$$

The total-intensity hyper-Rayleigh scattering experiment basically consists of measuring the amount of incoherently scattered optical second harmonic (parallel and perpendicular output polarizations) versus a reference. When only this single measurement is done, only one independent tensor component can be obtained. For charge transfer molecules, this is generally approximated by β_{zzz} . The depolariza-

tion measurement is generally performed with a rotating analyzer inserted between the scattering cell and photomultiplier, but with a reduced numerical aperture of the condensing system [21–23]. From the theoretical depolarization ratio calculated as a function of β_{zxx}/β_{zzz} (Eq. (22)), it is then possible to derive, from the experimentally observed depolarization ratio, the ratio of β_{zxx}/β_{zzz} . This then not only gives a value for β_{zxx} , but additionally a relative sign and a check on the assumption that β_{zzz} was responsible for most of the scattered light. For donor–acceptor charge transfer molecules, this is always the case. Measurement of the depolarization ratio for more complex molecules also reveals the tensorial nature of the hyperpolarizability [24].

From the complementary nature of EFISHG and HRS, application of both techniques to (neutral and dipolar) molecules can lead to the measurement of more tensor components, to the experimental determination of structural parameters [22], or to the independent confirmation of experimentally obtained values for hyperpolarizability tensor components [25].

Ever since HRS has been developed as an experimental technique to determine the first hyperpolarizability β of molecules in solution, it has been realized that multi-photon fluorescence is a competing nonlinear process, contributing to the HRS signal [26]. For the classical dipolar and neutral molecules that may exhibit multi-photon fluorescence, electric-field-induced second-harmonic generation (EFISHG) experiments are possible. However, for ionic and non-dipolar compounds, no electric field can be applied over the solution. Hence, no EFISHG measurements are possible. Then it is very tempting to rely on the HRS measurement only. When there is, however, a multi-photon fluorescence (MPF) contribution, an overestimation of the first hyperpolarizability value results [27].

A number of experimental approaches have been suggested to overcome this fluorescence contribution. Since the fluorescence has a very broad spectral signature, versus a narrow spectral response for the hyper-Rayleigh scattering, subtracting the background from the peak is feasible, but time-consuming [28]. A fundamental and elegant approach is based on the intrinsic difference in temporal profile between the immediate scattering and the time-delayed fluorescence [29]. The high-frequency demodulation of the multi-photon fluorescence is, in fact, the implementation in the Fourier domain of this approach. A straightforward way to obtain high modulation frequencies is by using the higher harmonics of the pulse repetition frequency of a femtosecond laser [30]. The use of the generic femtosecond pulse laser—the titanium–sapphire laser—then leads to a fundamental wavelength of around 800 nm. For second-order nonlinear optical effects, this wavelength often leads to strong two-photon resonance enhancement, due to the closeness of the second-harmonic wavelength and the wavelength of electronic absorption. Although this may facilitate the measurement of the enhanced hyperpolarizability, it also strongly suggests the use of longer wavelengths as the fundamental. Accurate knowledge of the dispersion of the first hyperpolarizability can lead to an assessment of the two-level model (see Section 8.3.1). With the use of a femtosecond optical parametric oscillator (OPO), accurately measuring the first hyperpolarizability β at the signal wavelengths of this OPO has now become possible [31]. Together with the measurements of β at the titanium–sapphire output wavelength itself, a significant dispersion of the first hyperpolarizability is now attainable.

To obtain a fluorescence-free hyperpolarizability value of these fluorescent chromophores, HRS experiments have to be performed at different amplitude modulation frequencies. The frequencies are the higher harmonics of the pulse repetition frequency (80 MHz). At each amplitude modulation frequency, an apparent hyperpolarizability value is calculated by the external reference method. Plotting the determined apparent hyperpolarizability value of the measured compound versus the applied amplitude modulation frequency then results in a typical demodulation curve. If no demodulation is observed, i.e., a constant value of the first hyperpolarizability versus frequency, no fluorescence contribution to the HRS signal is present. This indicates that the chromophore does not fluoresce; that the fluorescence present is spectrally filtered out; or that the fluorescence lifetime is too short for its corresponding demodulation to be observed within the bandwidth of the instrument. Much care has to be taken when interpreting the result, then. When there is an MPF contribution to the HRS signal, the fluorescence contribution will diminish for the higher modulation frequencies, since the fluorescence can no longer follow the modulated excitation. The same principle is applied in multi-frequency phase fluorometry to determine the fluorescence lifetime. The finite fluorescence lifetime(s) cause a delay between the excitation and the fluorescence. In the frequency domain, this temporal delay is translated to a phase shift between excitation and fluorescence, and thus a decrease in the amplitude of the fluorescence for increasing modulation frequencies. In the limit of high modulation frequencies, the fluorescence contribution is completely demodulated, essentially zero, and the measured signal is solely due to HRS. The apparent hyperpolarizability as a function of modulation frequency can be analyzed toward the fluorescence contribution and lifetime(s), and the intrinsic, fluorescence-free, hyperpolarizability in the high-frequency limit. Depending on the actual value for the fluorescence lifetime, this limit can be experimentally achieved (for long lifetimes), or its value has to be calculated from a high-frequency extrapolation. The technique of high-frequency demodulation of the MPF contribution has been successfully applied to newly designed chromophores that intrinsically show MPF, such as subphthalocyanines [32] and stilbazolium dyes [33]. It was also instrumental in validating the inclusion strategy as a promising technique, not only to induce non-centrosymmetry in the bulk, but also to increase the molecular nonlinearity [34]. The inclusion leads to a more rigid structure, thereby reducing the number of nonradiative relaxation pathways, and hence, inducing (multi-photon) fluorescence.

8.3 Second-order Nonlinear Optical Molecules

8.3.1 Dipolar Molecular Structures

Molecules are suitable for nonlinear optics devices, only if they satisfy several requirements [35]. Amongst others are demands, due to the high temperatures needed

Figure 1. Resonance forms of the benchmark 4-nitroaniline molecule.

for poling and the intense optical fields used in nonlinear optics, for a high thermal and photochemical stability. To improve device performance, the molecules must also have a high transparency and an optimized nonlinearity. Here we treat mainly the design of molecules with an optimized nonlinearity.

The general quantum chemical description of the nonlinear susceptibilities and hyperpolarizabilities in the density matrix formalism was developed by Bloembergen and Shen [36]. A simplification of this model for dipolar organic molecules, by only considering the transition between the ground state and the first excited state, led to the well-known two-state expression for the first hyperpolarizability [37] (Eq. (23)).

$$\beta_{zzz}(-2\omega; \omega, \omega) = \frac{3\Delta\mu_{eg,z}M_{eg,z}^2}{(\hbar\omega_{eg})^2} \frac{\omega_{eg}^4}{(\omega_{eg}^2 - 4\omega^2)(\omega_{eg}^2 - \omega^2)} \quad (23)$$

where $\Delta\mu_{eg,z}$, $M_{eg,z}$ and $\hbar\omega_{eg}$ are the dipole moment difference along the z -axis, the electronic transition moment along the z -axis, and the energy of transition, respectively, between the ground state and the first excited state. The contribution from bond-additivity in Ref. [37] was shown not to contribute to β [38]. The first factor corresponds to the intrinsic value of the hyperpolarizability for $\omega = 0$, β_0 , and the second factor is the dispersion factor. This model is a widely used tool to describe the β response in terms of the electronic and spectroscopic properties of organic molecules.

The charge distribution in the ground and first excited state of dipolar donor–acceptor-substituted molecules can be described in terms of the resonance forms in Figure 1. For donor–acceptor-substituted aromatic conjugated systems, the ground state is described mainly by the first resonance form. Upon excitation, an electron is transferred from the donor to the acceptor, a strong increase in the dipole moment occurs, and the charge distribution in the excited state is described better by the second resonance form. For aromatic systems, increasing donor and acceptor strengths, and lengthening the conjugated bridge, are approaches that have led to significant improvements in β .

Marder et al. have shown that an increase in donor and acceptor strength does not necessarily result in an increase in β_0 for donor–acceptor-substituted polyenes, but that β_0 has a sinusoidal evolution with the donor and acceptor strength [39]. The evolution of $\Delta\mu_{eg,z}$, $M_{eg,z}$, and $\hbar\omega_{eg}$ appearing in the parameters of the static hyperpolarizability β_0 was calculated semi-empirically [40, 41]. If the donor and acceptor strength increase, the polarization of the ground state will also increase. The structural parameter used to describe the ground-state polarization is the average difference in length between adjacent carbon–carbon bonds in the polyenic

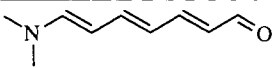

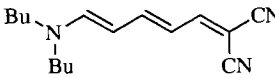

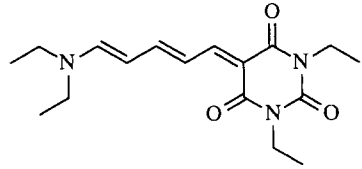

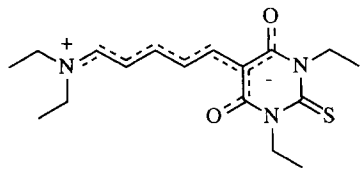

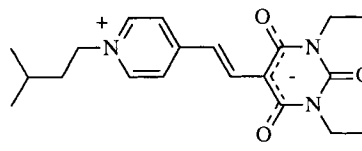

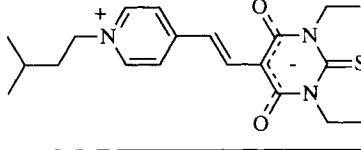

bridge, or bond order alternation (BOA). Initially, an increase in donor and acceptor strength leads to an enhancement of β_0 ($-11 \text{ pm} > \text{BOA} > -4 \text{ pm}$). An optimum in the hyperpolarizability is found for polyenes having an intermediate BOA value ($-4 \pm 1 \text{ pm}$) [42]. If the donor and acceptor strength increase further, both resonance forms will contribute equally to the ground state and first excited state. The polyene ground-state structure is then that of a symmetric cyanine ($\text{BOA} \approx 0$) and $\beta_0 \approx 0$ because of the small polarity difference between the ground state and excited state ($\Delta\mu_{\text{eg},z} \approx 0$). Thus, β_0 decreases for $-4 \text{ pm} > \text{BOA} > 0 \text{ pm}$. As the donor and acceptor strength increase even further, the ground-state structure is described by the charge-separated canonical form, $11 \text{ pm} > \text{BOA} > 0 \text{ pm}$. Since the first excited state is then described by the first resonance form, $\Delta\mu_{\text{eg},z} < 0$ and $\beta_0 < 0$. Experimental evidence for the calculated evolution was presented in a series of papers [43–47]. An example of the observed evolution of the parameter $\mu\beta_0$ with donor–acceptor strength is given in Table 3. The ground-state dipole moment increases monotonically with increasing ground-state polarization.

Based on the BOA theory, Barzoukas and Blanchard-Desce developed a two-state two-form model for the β_0 of push–pull compounds [48]. The β_0 was expressed as a function of the newly defined parameter *MIX*, which is related to the degree of mixing between the neutral and zwitterionic resonance forms in the ground and excited state. This treatment has the advantage of conceptual simplicity and that it relies on a structural parameter that can be more easily used for other push–pull molecular systems than polyenes. The evolution of β_0 observed with *MIX* is identical to that with BOA. The BOA theory was later also used to optimize the figure-of-merit of dyes for photorefractive applications [49, 50].

This theory yielded valuable guidelines for the further optimization of the β_0 of aromatic systems. These systems are not able to pass the peak of the β_0 curve due to the large ground-state aromaticity that limits the electronic polarizability. A further optimization was thus achieved by increasing the ground-state polarization through the use of conjugated systems with lower aromaticity [51] and stronger electron acceptors [52]. Simultaneously, functional groups were introduced to improve the processability and stability of the chromophores and to prevent chromophore–chromophore interactions. The substitution of a chromophore with bulky alkyl groups reduces the risk of unwanted chromophore aggregation in the solid state and improves the translation of a large hyperpolarizability into a large second-order nonlinearity [53]. An example of such a chromophore is given in Figure 2 [54].

Apart from purely electronic effects, an asymmetric nuclear relaxation in the electric field can also contribute to the first hyperpolarizability in processes that are partly induced by a static field, such as the Pockels effect [55, 56], and much attention is currently devoted to the study of the vibrational hyperpolarizability, β_v . β_v can be deduced from experimental data in two different ways [57, 58], and a review of the theoretical calculations of β_v is given in Refs. [59] and [60]. The numerical value of the static β_v is often similar to that of static electronic hyperpolarizabilities, and this was rationalized with a two-state valence-bond charge transfer model. Recent ab-initio computational tests have shown, however, that this model is not always adequate and that a direct correlation between static electronic and vibrational hyperpolarizabilities does not exist [61].

8.3.2 Rigid Multichromophoric Molecules

Since the first nonlinear susceptibility $\chi^{(2)}$ is a third-rank tensor, it is only non-zero in non-centrosymmetric media. To break the centrosymmetry of the macroscopic media, poling techniques using optical and electric fields have been developed, or use was made of the inherent polar ordering in Langmuir–Blodgett films and crystals with non-centrosymmetric point groups.

It is also possible to covalently bind dipolar molecules together in a non-centrosymmetric conformation. In this approach, the requirement of molecular

Figure 2. Example of a chromophore optimized for electro-optic applications. A PMMA-doped film with this chromophore had $r_{33} = 83 \text{ pm V}^{-1}$.

alignment is partly incorporated at the molecular level. Theoretically, this can result in a significant enhancement of the nonlinear susceptibility tensor. If n dipolar molecules with dipole moment μ_M and a dominant hyperpolarizability tensor component β_M along the dipole moment are covalently bonded together in a parallel fashion, the resulting multimer will have dipole moment $n\mu_M$ and hyperpolarizability $n\beta_M$. For a polymer film with a number density of N_M multimers and poled by a poling field with amplitude E , the macroscopic nonlinear susceptibility is equal to:

$$\chi_{ZZZ}^{(2)} = \frac{n^2 N_M f^2(\omega) f(2\omega) \mu_M \beta_M E}{5kT} \quad (24)$$

or n times the susceptibility of a poled film with nN_M monomer number density. Here we have assumed that, to a first approximation, there are no changes in the electronic structure due to intramolecular dipolar interactions. Note that this enhancement in the nonlinear susceptibility is only obtained by an improved orientation, and does not result in a transparency loss.

In addition to this enhancement, several other effects can be induced by the new conformation at the microscopic scale, such as the appearance of off-diagonal molecular hyperpolarizability tensor components. The study of these microscopically aligned molecules has also provided new fundamental insights and was only made possible through creative synthetic chemistry. The systems that have been studied so far include dimers and tetramers such as the binaphthyl ethers and the calixarenes, and polymers with rigid backbones that force the pendant D- π -A chromophores into a non-centrosymmetric conformation.

Tetramers: calixarenes

In a calixarene, four dipolar donor-acceptor molecules are covalently bonded in a non-centrosymmetric conformation [62, 63]. As shown in Figure 3, a functionalized calix[4]arene can occur in four different extreme conformations with different relative orientations of the NLO-phores: *cone*, *paco*, *1,2-alt* and *1,3-alt*. If the donor groups are alkylated by groups larger than ethyl, the different conformations are

Figure 3. Molecular structure of a propoxycalix[4]arene in the *cone* conformation and a schematic representation of the four possible calix[4]arene conformations. A, electron-accepting group.

not interconvertible [64]. Since the synthesis starts from cyclophanes of four phenol moieties connected by methylene bridges, the electron donor groups are ether groups.

For the *cone* conformation, and with propoxynitrostilbene as a constituent chromophore, a threefold improvement in the static hyperpolarizability β_0 and tenfold improvement in $\mu\beta_0$ were reported for the calixarene compared with the monomeric chromophore, methoxynitrostilbene [65]. Upon poling of calixarenes in a thin film, a higher degree of orientation than for single D- π -A systems was observed.

The hyperpolarizability tensor of the four tetranitropropoxycalix[4]arene conformers using hyper-Rayleigh scattering (HRS) was studied systematically by Kenis et al. [66]. The dihedral angles of the four conformers (the angle between the planes of the different *p*-nitropropoxyphenyl units and the molecular plane through the four methylene groups that connect the four chromophoric units) were calculated by molecular dynamics and compared with the values from X-ray diffraction. The relative values of the hyperpolarizabilities of the different conformers could be well accounted for by using an additive approach for the calixarene hyperpolarizability. In this approach, the four chromophoric units are considered to contribute independently to the hyperpolarizability of the calixarene, which is calculated by performing a coordinate transformation of the monomeric hyperpolarizability tensor components to the coordinate system of the calixarene and adding the four contributions. A review of this approach used to analyze the hyperpolarizability tensor of rigid multi-chromophoric molecules is given in Ref. [67]. Although the 1,2-*alt* and 1,3-*alt* conformations can be considered as being close to centrosymmetry, this calculation showed that the relatively large hyperpolarizability for these conformations (β_0 is 1/2 and 1/4 of the cone conformation, respectively) could be attributed to an octopolar contribution in the calixarene hyperpolarizability.

Sum-over-state calculations by Morley and Naji [68] have shown that, for *cone* tetranitropropoxy[4]calixarene, steric interactions force the propoxy donor groups into an orientation that does not allow an optimal overlap of the oxygen donor lone

Figure 4. Structural formula and simplified geometry of a binaphthyl ether derivative. A is an electron acceptor. In the simplified geometry, β_{zzz} is in a plane parallel to the XZ -plane.

pairs with the conjugated system. This effect should reduce the total hyperpolarizability of the *cone* conformer. The evolution of the calixarene β with respect to changes in conformation was studied theoretically by Brouyère et al. [69]. According to these calculations, strong π - π cofacial interactions shift the calixarene charge transfer bands to shorter wavelengths.

Dimers: binaphthol and carbazole derivatives

An interesting class of multi-chromophoric chromophores are the binaphthol derivatives. In this class of molecules, two naphthyl ether units are covalently attached to each other in the 1,1'-positions, as shown in Figure 4 [70–72].

Apart from the possibility of obtaining a larger hyperpolarizability, these molecules are also interesting since they occur as two enantiomers. The molecular geometry of the binaphthyl rings is not planar due to the steric interactions between the hydrogen atoms in the 8,8'-positions as the molecule approaches planarity [73]. From the geometry in Figure 4, it is clear that the binaphthyl ethers cannot be superimposed on their mirror image, and hence are axially chiral. A free interconversion between the two forms does not occur at room temperature. If the starting point for the synthesis is optically pure 2,2'-dihydroxy-1,1'-binaphthyl, optically pure push-pull binaphthol derivatives can be prepared, with an ether group as electron donor. Since chiral molecules guarantee a non-centrosymmetric point group in the crystalline phase, it was anticipated that this family of compounds would provide crystals with large susceptibilities.

The hyperpolarizability tensor components of the dimer can again be calculated using an additive approach for the dimer hyperpolarizability. In the dimer coordinate frame, which has the C_2 axis as Z -axis, the dimer hyperpolarizability tensor components are:

$$\beta_{ZZZ} = 2 \left(\cos \frac{\theta}{2} \right)^3 \beta_{\text{mono}} \quad (25)$$

$$\beta_{ZXX} = \beta_{XZX} = \beta_{XXZ} = 2 \left(\cos \frac{\theta}{2} \right) \left(\sin \frac{\theta}{2} \right)^2 \beta_{\text{mono}} \quad (26)$$

where β_{mono} is the dominant β_{zzz} tensor component of the dipolar subunit. A series of binaphthol derivatives was studied using a combination of HRS and EFISHG [25, 74]. Each of these techniques measures a different combination of the two tensor components of the dimer (see Eqs. (21) and (19)):

$$\beta_{\text{HRS}} = \sqrt{\frac{6}{35} \beta_{ZZZ}^2 + \frac{16}{105} \beta_{ZZZ} \beta_{ZXX} + \frac{38}{105} \beta_{ZXX}^2} \quad (27)$$

$$\beta_{Z, \text{EFISHG}} = \beta_{ZZZ} + \beta_{ZXX} \quad (28)$$

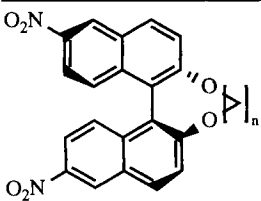

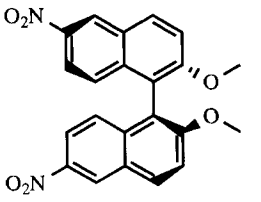

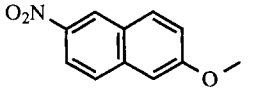

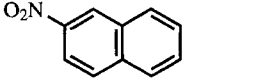

The dihedral angle was determined using AM1 semi-empirical calculations and X-ray diffraction. β_{mono} was then calculated independently of both β_{HRS} and β_{EFISHG} . The results are summarized in Table 4.

The close agreement between the β_{mono} as calculated from HRS and EFISHG again demonstrates the validity of the additive approach for the dimer hyperpolarizability. If the molecule is forced into a more planar conformation, a blue shift of the charge transfer absorption band occurs and β_{mono} is reduced substantially. This effect is attributed to the increased ring strain that reduces the overlap of the oxygen donor electron pairs with the conjugated system. Thus, for $n = 1$, the oxygen donor pairs are virtually noninteracting with the conjugated system, and the β_{mono} is almost equal to that of 2-nitronaphthalene. As n increases, the ring strain is reduced, and β_{mono} evolves to that of 6-nitro-2-methoxynaphthalene. Simultaneously, β_{ZXX} increases in magnitude relative to β_{ZZZ} , from $\beta_{ZXX}/\beta_{ZZZ} = 3/19$ for $n = 1$ to $\beta_{ZXX} = \beta_{ZZZ} = 19$ for $n = 4$.

The crystallization of binaphthol derivatives yielded crystals of low quality, probably because of the large dimer dipole moment and the nonplanar molecular shape [75]. X-ray diffraction was done on the chiral (*S*)-2,2'-diethoxy-1,1'-binaphthyl-6,6'-dicarbaldehyde. The crystallographic spacegroup was $P4_32_12$. Analysis of the unit cell showed that all the dipole moments along the dimer twofold axis cancel symmetrically, even though the space group of the optically pure enantiomer is non-centrosymmetric. For this space group all the nonlinear susceptibility tensor components disappear, and no frequency doubling was observed in a Kurtz-Perry powder test.

A significant enhancement of the off-diagonal tensor components, β_{ZXX} and β_{XZX} , was reported for C_{2v} -symmetric benzene [76] and carbazole derivatives [77]. For the carbazole derivatives, the amino donor is shared by the two acceptor groups, and quantum chemical calculations confirmed the existence of a two-dimensional charge transfer transition. A combination of (depolarized) HRS and EFISHG measurements showed that $\beta_{ZXX} = \beta_{XXZ} = \beta_{XZX}$ and $\beta_{ZZZ} = 0.28\beta_{ZXX}$

[24]. Due to these large off-diagonal components, a poled film of a 3,6-substituted carbazole derivative has $d_{31} = d_{33}$ [78]. A similar enhancement of the off-diagonal tensor components was also verified for C_{2v} -symmetric benzene derivatives with EFISHG and HRS experiments.

It has been shown that poled films of molecules with large off-diagonal tensor components show a slower relaxation than poled films of dipolar molecules having only a β_{zzz} tensor component [79]. Frequency doubling through the off-diagonal components possibly offers the advantage of better phase-matching because of the almost equal refractive indices for the ω and 2ω waves, and a reduced absorption of the frequency-doubled wave in a poled film [80]. More success in obtaining non-centrosymmetric crystals was reported for the dimers of 4-nitroaniline bonded together via a methylene bridge in a Λ -shaped conformation [81]. Similarly, a dimer with a roof-shaped conformation crystallized in a crystal with large $\chi^{(2)}$ [82]. A re-

Figure 5. General structure of a triphenylcarbinol derivative.

view of these molecules and polysiliciated multi-dipolar compounds is given in Ref. [83]. A detailed determination of the crystal structure of the dimer 2,6-bis(4-hydroxybenzylidene)cyclohexanone and its implications for the nonlinear optical coefficients has been reported [84]. The Λ -shaped molecules of Heppke and co-workers form liquid crystals, of which an initial nonpolar mesophase could be converted into a polar state by applying an electric field of a few volts per micrometer, and nonlinear coefficients d_{31} as large as 16 pm V^{-1} have been reported [85]. The first hyperpolarizabilities of these Λ -shaped molecules were determined by hyper-Rayleigh scattering [86].

Trimers: triphenylcarbinol derivatives

The triphenylcarbinol derivatives have the general structure shown in Figure 5 [87]. It should be noted, however, that these molecules are not conformationally rigid at room temperature since a rapid rotation around the α -bond occurs. This conformational flexibility complicates the data analysis. The time-averaged dipole moment from capacitance measurements was not significantly larger for the trimer than for the monomeric reference compounds. The hyperpolarizability calculated from HRS measurements only showed a significant increase for the triphenylcarbinol derivative of methoxynitrostilbene compared with that of monomeric methoxynitrostilbene. These results indicate that triphenylcarbinol exists in various conformations, and that the average structure possibly has significant octopolar character. Other examples of correlated molecules with octopolar symmetry will be discussed in Section 8.3.3.

Polymers

The attachment of several chromophores to a rigid polymeric backbone can also lead to a significant enhancement of the overall hyperpolarizability and dipole moment of the polymer. The three polymeric conformations that have been shown to affect the overall nonlinear response are schematically depicted in Figure 6. They include I) polymers with a helical backbone and pendant groups that have a fixed orientation relative to the axis of the central helix, II) dendrimers with pendant chromophores attached in the outer shell, and III) main-chain polymers with a rigid backbone.

Figure 6. Polymeric geometries that lead to a microscopic orientation of the attached nonlinear optical chromophores and affect the nonlinear optical response.

Examples of helix-forming polymers are poly(isocyanides) and poly(glutamates). The repeat units of these polymers are shown in Figure 7. For poly(isocyanides), each carbon atom of the polymer backbone was functionalized with a nonlinear optical chromophore (Figure 7, I). Because of large steric interactions between the

Figure 7. Structural formula of the repeat units of the functionalized I) poly(isocyanide) and II) poly(γ -benzyl-L-glutamate) polymers that adopt a helical conformation in solution.

bulky chromophores, a planar conformation or conformations combining *R* and *S* helices is unfavorable, and the most probable conformation is a full *R* or *S* helix with 3.8 pendant chromophores per turn at an angle of 60° with the central helix [88]. The investigated samples had a total of 100 chromophores per polymer. The actual increase in the polymer hyperpolarizability was smaller than calculated on the basis of the proposed conformation and the monomer hyperpolarizability, but was still a substantial factor of 5–10. More important, the off-resonant $\mu\beta$ product extrapolated from EFISHG measurements for the polymer was found to be a factor of 1.5 larger than would be found for an uncorrelated assembly of the same proportion of chromophores.

The first report of an enhanced nonlinearity due to the formation of an organic superstructure was for an α -helix forming poly(γ -benzyl-L-glutamate) of molar mass 550 000 g mol⁻¹, where the total dipole moment was 6000 D and a polymer nonlinear polarizability of 500×10^{-30} esu was found [89]. A poly(γ -benzyl-L-glutamate) copolymer with 16 % functionalized groups and an average degree of polymerization of 77 was later synthesized (Figure 7, II) and studied with a combination of EFISHG and dipole moment measurements [90]. For the superstructure, a dipole moment of 460 D and a static $\mu\beta$ of $119\,000 \times 10^{-30}$ esu were found, which represent an enhancement in $\mu\beta$ by a factor of 35 over a system of uncorrelated chromophores.

Poly(propylene imine) dendrimers of generations 4, 8, 16, 32, and 64 were functionalized with the dipolar chromophore 4-dimethylaminophenylcarboxamide end groups [23]. Even though the packing of the chromophores around the dendritic core results in a reduction of the nonlinearity (Figure 6, II), valuable information about the dynamics and rigidity of the dendrimers was obtained. The nonlinear optical response was studied by HRS. For the lower generations of dendrimers (4, 8, and 16) the hyperpolarizability calculated for the whole dendritic structure increases linearly with the number of chromophores. At higher concentrations, this increase becomes smaller and eventually disappears. This evolution shows that, at low generations, the pendant chromophores behave essentially independently, whereas at higher generations the conformational freedom is restricted and a rigid, sphere-like structure is formed. From the concentration dependence of the chemical shift of the amide protons it was concluded that intradendritic hydrogen bonding assists in the formation of a more rigid structure for the higher generations.

Enhancement of $\mu\beta$ in rigid multi-chromophore systems was also reported for main-chain polymers [91]. In these polymers, a head-to-tail alignment of the dipolar chromophores will result in an overall larger nonlinearity (Figure 6, III). A series of small oligomers with head-to-tail dipolar chromophores exhibited significant dipole moment additivity in both solution and polymer film [92]. An enhancement by 1.6-fold was reported for the electro-optic coefficient of a film of the tetramer compared with a film of analogous monomer. A large fraction of the homopolymers with dipolar repeat units had low solubility, which prevented further characterization. For an AB copolymer of α -cyano-*m*-methoxy-*p*-(ω -oxypropoxy)-cinnamate with ω -hydroxydodecanoate, an enhancement of $\mu\beta$ by a factor of 20 was found in EFISHG experiments, but this enhancement was not observed in thin films [93]. Recently, a strong cooperative enhancement effect by a factor of 40 was reported for a liquid crystalline head-to-tail 50/50 copolymer

of 2-nitro-4-carboxy-4'-[N-(11-hydroxyundecyl)-N-methylamino]azobenzene and 4-carboxy-4'-[N-(11-hydroxyundecyl)-N-methylamino]azobenzene [94].

A complex multi-chromophoric system comprises the purple membrane patches from *Halobacterium salinarium*. These patches are composed of about 3000 bacteriorhodopsin proteins. The hyperpolarizability of solubilized monomeric bacteriorhodopsin was measured by HRS and found to be 2100×10^{-30} esu at 1064 nm. This high value is due to the presence of a chromophore in the protein, the protonated Schiff base of retinal. A purple membrane patch can be treated as a two-dimensional crystal of bacteriorhodopsin proteins, and its structure is known in considerable detail. The analysis of the purple membrane tensor was performed by adding the hyperpolarizabilities of the individual proteins in the purple membrane. From (depolarized) HRS measurements on purple membrane suspensions, the structure of the purple membrane patches, and an average membrane size measured by atomic force microscopy, a β value of 2200×10^{-30} esu was calculated for bacteriorhodopsin [22]. The organization of the dipolar protonated Schiff base chromophores in the membranes was found to be predominantly octopolar.

8.3.3 Octopolar Molecules

In the early 1990s, octopolar molecules were introduced in the field of second-order nonlinear optics [95]. In contrast to dipolar molecules where it is favorable to have a large change in dipole moment upon excitation in order to maximize β , octopolar molecules are nonpolar molecules that combine second-order nonlinear optical properties with a strict cancelation of all vector-like observables, including the ground- and excited-state dipole moment. Consequently, the hyperpolarizability of such molecules cannot be described by the classical two-level model, since the difference between excited- and ground-state dipole moments $\Delta\mu_{ge}$ cancels. Zyss and co-workers used a three-level system containing the ground state and a double-degenerate excited state to describe the hyperpolarizability of octopoles [96, 97]. The expression for β within this model is:

$$\beta = \frac{3}{2} \frac{M_{eg}^2 M_{ee}}{(\hbar\omega_{eg})^2} \frac{\omega_{eg}^4}{(\omega_{eg}^2 - 4\omega^2)(\omega_{eg}^2 - \omega^2)} \quad (29)$$

with M_{ee} the transition dipole moment connecting the degenerate states. Note that the dispersion behavior of β is similar to that of the two-level description (Eq. (23)).

Furthermore, Lee et al. used a four-state model to describe the NLO properties of an octopolar molecule such as crystal violet [98]. In addition, they showed that one can use the concept of bond order alternation (BOA) to analyze the NLO structure–property relationship in octopolar molecules.

Prior to discussing the properties of octopolar molecules, it is instructive to consider first some of the basic properties of tensors. In general, any tensor of rank n can be decomposed in a sum of so-called irreducible tensors $T_{(n)}^{(\gamma, J)}$ that are invariant under three-dimensional rotation [99]:

$$T(n) = \sum_{\oplus \gamma, J} T_{(n)}^{(\gamma, J)} \quad (30)$$

Equation (30) is called the reduction spectrum of the tensor $T(n)$. Each irreducible tensor $T_{(n)}^{(\gamma, J)}$ of rank n and weight J has 3^n components labeled by n indices, and its 3^n components form the basis of an irreducible representation of the three-dimensional rotation group of degree $2J + 1$. Hence, each irreducible tensor with weight J has $2J + 1$ independent components. The superscript γ distinguishes between different components of identical weight. For example, the reduction spectrum of the hyperpolarizability tensor β (rank three) is:

$$\beta(3) = \beta_{(3)}^{(0)} + \beta_{(3)}^{('1)} + \beta_{(3)}^{('',1)} + \beta_{(3)}^{('',1)} + \beta_{(3)}^{('2)} + \beta_{(3)}^{('',2)} + \beta_{(3)}^{(3)} \quad (31)$$

In addition, it can be shown that each irreducible tensor of rank n and weight J can be expressed as an irreducible tensor of rank J (the natural form of the tensor). Natural tensors of rank (and weight) 0, 1, 2, 3 are called scalars, vectors, deviators, and septors, respectively. The corresponding physical properties are said to have a scalar ($J = 0$), dipolar ($J = 1$), quadrupolar ($J = 2$), and octopolar ($J = 3$) character.

For the hyperpolarizability of purely octopolar molecules, all irreducible tensorial components of weight strictly lower than three cancel due to symmetry requirements and $\beta = \beta_{(3)}^{(3)}$ [99]. For other molecules, the hyperpolarizability can contain contributions of all irreducible tensor components, depending on the symmetry of the molecule.

Let us clarify this by considering the two hypothetical molecules shown in Figure 8. Molecule **a** is a typical dipolar donor–acceptor molecule with C_{2v} symmetry and

Figure 8. Schematic representation of a) a typical dipolar donor–acceptor molecule with C_{2v} symmetry and b) a purely octopolar molecule with D_{3h} symmetry.

molecule **b** is a purely octopolar molecule with D_{3h} symmetry. Molecular symmetry considerations reduce the number of independent β coefficients which can be further reduced by Kleinman index permutation symmetry. Under this condition, the non-vanishing hyperpolarizability components for the C_{2v} symmetry group are zzz , $zxx = xzx = xxz$, $zyy = yzy = yyz$ (the hyperpolarizability components are represented by their Cartesian coordinates) [3]. In addition, for two-dimensional molecules like **a** all y -containing β coefficients can be assumed negligible. The hyperpolarizability can be represented in a simplified form as a 3×6 matrix [3],

$$\beta = \begin{bmatrix} 0 & 0 & 0 & 0 & zxx & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ zxx & 0 & zzz & 0 & 0 & 0 \end{bmatrix} \quad (32)$$

Under the assumption of Kleinman symmetry, the hyperpolarizability tensor is fully symmetric and the reduction spectrum simplifies to

$$\beta(3) = \beta_{(3)}^{(1)} + \beta_{(3)}^{(3)} \quad (33)$$

Following standard procedure [99], the vector part of the hyperpolarizability of molecule **a** is

$$\beta_1^1 = \begin{bmatrix} 0 \\ 0 \\ zzz + zxx \end{bmatrix} \quad (34)$$

which can be embedded into a third-rank tensor

$$\beta_3^1 = \frac{1}{5} \begin{bmatrix} 0 & 0 & 0 & 0 & zzz + zxx & 0 \\ 0 & 0 & 0 & zzz + zxx & 0 & 0 \\ zzz + zxx & zzz + zxx & 3(zzz + zxx) & 0 & 0 & 0 \end{bmatrix} \quad (35)$$

The septor part is given by

$$\beta_3^3 = \frac{1}{5} \begin{bmatrix} 0 & 0 & 0 & 0 & 4zxx - zzz & 0 \\ 0 & 0 & 0 & -zxx - zzz & 0 & 0 \\ 4zxx - zzz & -zxx - zzz & 2zzz - 3zxx & 0 & 0 & 0 \end{bmatrix} \quad (36)$$

In Figure 9 we plotted the ratio of the magnitude (square root of the sum of the squares of all components) of the vector part and the septor part $|\beta_3^1|/|\beta_3^3|$ vs. β_{zxx}/β_{zzz} for molecules with only two independent hyperpolarizability components

Figure 9. $|\beta_3^1|/|\beta_3^3|$ vs. β_{zxx}/β_{zzz} for a hypothetical molecule with only two independent β tensor components.

(such as molecule **a**). $|\beta_3^1|/|\beta_3^3|$ peaks when $\beta_{zxx}/\beta_{zzz} = 0.3$, showing a dominant dipolar contribution.

However, for most other ratios of β_{zxx}/β_{zzz} the octopolar contribution to the nonlinearity is dominant. The dipolar contribution to the hyperpolarizability completely vanishes when $\beta_{zxx}/\beta_{zzz} = -1$ and the molecule is purely octopolar. This situation occurs for molecule **b** with purely octopolar D_{3h} symmetry and non-vanishing hyperpolarizability components $zzz = -zxx = -xxz = -xzx$. The hyperpolarizability tensor then reduces to

$$\beta = \beta_3^3 = \begin{bmatrix} 0 & 0 & 0 & 0 & -zzz & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ -zzz & 0 & zzz & 0 & 0 & 0 \end{bmatrix} \quad (37)$$

One property that makes octopoles interesting is the lack of dipole moment in the ground state. This should increase the probability of non-centrosymmetric crystallization and prevent detrimental dipolar (aggregate) interaction. In addition, the ratio of off-diagonal versus diagonal β tensor components is higher than that for traditional dipolar systems, which opens up the possibility of less stringent polarization schemes for parametric and electro-optic processes [95]. Furthermore, it has been shown that the efficiency–transparency trade-off favors octopolar molecules over traditional dipolar molecules [96].

Since octopolar molecules lack a dipole moment, the hyperpolarizability of purely octopolar molecules cannot be determined with the EFISHG technique. Therefore, the experimental determination of these nonpolar molecules remained a problem until the development of the hyper-Rayleigh scattering technique (HRS). As explained in Section 8.2.2, HRS provides a sensitive tool for the determination of the hyperpolarizability of nonpolar molecules in solution.

One of the first octopoles that was shown to have a considerable second-order nonlinearity is the highly polarizable cyanoform anion, which belongs to the purely octopolar symmetry group D_{3h} [100]. The β_{zzz} of the cyanoform anion as measured by HRS was found to be on the order of 7×10^{-30} esu. Other octopoles that have been investigated include tetraorganotin compounds, symmetrically substituted benzenes and triazines, and tertiary amines [101–105]. Recently, a number of very efficient octopolar structures have been identified. For example, the octopolar crystal violet cation was shown to be considerably nonlinear, with a hyperpolarizability at least five times higher than the traditional dipolar benchmark molecule dimethylaminonitrostilbene (DANS) [106].

8.3.4 Metallo-organic Compounds

Although the search for organic materials displaying high NLO properties has been a continuously expanding domain for many years, the field of metallo-organic nonlinear optics is rather young and unexplored. In the last decade, researchers only sporadically investigated the NLO properties of metallo-organic compounds, and just recently have they begun a more systematic investigation of the molecular properties that determine the NLO response of these metallo-organic complexes. Today, this new class of materials is recognized to have potential for NLO purposes, particularly because they show strong absorption bands (metal-to-ligand charge transfer, MLCT and ligand-to-metal charge transfer, LMCT) in the UV–Vis region. As these are associated with low transition energies and high transition dipole moments the two-level model predicts large hyperpolarizabilities for metallo-organic molecules [36]. Further, numerous types of geometry are available, as a palet of coordination patterns is at hand for metals. Multipolar species become accessible and/or the molecular hyperpolarizability can be manipulated by small changes in ligands, even in the NLO-inactive ones. In addition, the possibility of chirality, which may induce a non-centrosymmetrical crystallization, can lead to a useful macroscopic arrangement. Good summaries of the NLO work performed on metallo-organic compounds can be found in several recent review articles [7, 106–109]. In this section we will focus on those metallo-organic compounds that have been proven successful in recent years (see Figure 10).

In 1987, Green et al. had already drawn attention to metallo-organic species for NLO when they revealed a SHG efficiency as high as 62 times that of urea for *cis*-[1-ferrocenyl-2-(4-nitrophenyl)ethylene] [110]. Nevertheless, it took three years before a profound EFISHG study of the molecular properties governing the hyperpolarizability of metallocenes was performed [111, 112]. Analogously to organic systems, the prolongation of the conjugated bridge, as well as the addition of electron-donating substituents (e.g., methyl groups) to the metallocene donor, was shown to enhance the hyperpolarizability. Further, the donor strength of ferrocene resembled that of the organic methoxyphenyl donor. Yet ferrocenes were expected to be stronger donors, on the basis of their binding energies and redox potentials. The discrepancy between the expected and the observed electron donor efficacy was ascribed to the poor coupling of the metal and the organic π -system which may

Figure 10. Metallo-organic complexes for nonlinear optics.

reduce the donor properties of the metal center in these *out-of-plane* structures. Calabrese et al. suggested the use of *in-plane* metallo-organic complexes, i.e., complexes with the MLCT in the plane of the organic π -system, to obtain large NLO efficiencies (Figure 11) [112].

Notwithstanding the drawbacks associated with the *out-of-plane* geometry, a series of conjugated ferrocene compounds with heterocyclic acceptors have recently been shown to exhibit large resonantly enhanced $\mu\beta$ values up to 3000×10^{-48} esu. Again, the increase in conjugation length or acceptor strength clearly led to en-

Figure 11. Examples of *out-of-plane* and *in-plane* complexes.

hanced hyperpolarizabilities [113]. On the other hand, substitution of Fe(II) with Ru(II) results in a blue shift and a clear reduction of the NLO efficiency, in accordance with the higher reduction potential of ruthenium [112, 113]. Nevertheless, the ruthenium complexes display a better nonlinearity-transparency trade-off.

In contrast to most organic compounds, two optical transitions contribute significantly to the optical nonlinearity of metallocene complexes [112, 114, 115]. In this regard, several hypotheses have been made on the nature of these transitions (Figure 12). Earlier models attribute the low-energy transition to either a ligand-field d-d excitation (**a**) or an MLCT transition to a bridge-localized LUMO+1 molecular orbital (**b**), while the high-energy transition is proposed to originate from a transition between either the metal (**a**) or a bridge-localized HOMO-3 orbital (**b**) and the acceptor-based LUMO. However, a more recent model by Barlow et al. (**c**) assumes the metal to the acceptor-centered LUMO and the bridge-localized HOMO-3 to the LUMO to be the low- and high-energy transitions respectively [115]. The latter hypothesis perfectly predicts the photoelectron, electrochemical and NLO properties of ferrocenes and ruthenocenes. An important consequence for the discussion of NLO properties of metallocenes is that the two-level model no longer holds for this class of materials.

Recently, the quadratic hyperpolarizabilities of heterobimetallic metallocenes have also been studied using the HRS technique [116–118]. The addition of a metal-pentacarbonyl function to a pyridyl acceptor group appeared to substantially increase the NLO efficiencies of the ferrocene-pyridyl compound [117, 118]. Notwith-

Figure 12. Schematic representation of the different hypotheses on the CT contributions to the molecular hyperpolarizability.

standing some inconsistencies between the studies of Lee et al. and Mata et al. concerning the magnitude of the hyperpolarizabilities, they both demonstrate the role of the metacarbonyl group in these complexes to be that of an inductive acceptor, lowering the energy of the pyridyl-centered LUMO [119]. Therefore the hyperpolarizability follows the series $\text{Cr}(\text{CO})_5 < \text{Mo}(\text{CO})_5 < \text{W}(\text{CO})_5 < \text{Mn}(\text{CO})_5^+ < \text{Re}(\text{CO})_5^+$. The improvement of the acceptor strength in this series is confirmed by a positive shift of the reduction potential of the Fe(II)/Fe(III) couple. Recently, the group 6 metal pentacarbonyl function was also proven successful as an acceptor in Fischer-type carbene complexes and amino-substituted cumulenylidenes [120, 121]. For these compounds, the differences in acceptor strength between Cr(0) and W(0) are less pronounced.

In another approach, transition metals have been used to stabilize the chemically reactive sesquifulvalene [116, 122]. In an early report, the bimetallic (Fe–Cr) complex was reported to exhibit hyperpolarizabilities up to 570×10^{-30} esu. However, for some other ferrocene derivatives of the sesquifulvalene complexes multi-photon luminescence has been observed which prohibits the determination of the hyperpolarizability by HRS. However, replacement of Fe(II) by Ru(II) results in luminescence-free derivatives [122, 123]. Monometallic manganese(I) sesquifulvalene complexes, on the other hand, are reported to exhibit only modest hyperpolarizabilities [124].

Aside from metallocene derivatives, *in-plane* metallo-organic complexes have been the subject of a number of NLO investigations. Formerly, large hyperpolarizabilities had been found for several mixed-valence bimetallic ruthenium complexes [125–127]. Moreover, for this class of molecules an intervalence charge transfer (IVCT) transition was suggested to account for the augmented hyperpolarizability. Confirmation was found in Stark (or electroabsorption) spectroscopy, which revealed large differences in dipole moment to accompany this low-energy IVCT transition [128].

During the last few years, a systematical study of gold(I), nickel(II), and ruthenium(II) σ -arylacetylide complexes has been performed by Whittall and co-workers. The hyperpolarizabilities were found to increase from the 14-electron gold complexes to the 18-electron nickel complexes and further to the 18-electron, more oxidizable, ruthenium compounds. Moreover, the influences of different types of π -systems, chain lengthening, acceptor, and ligand have been investigated [129–134]. As expected, the molecular hyperpolarizability relates to the chain length and acceptor strength. Changes in the metal periphery, though, only have a limited influence for these compounds. Similar results are obtained by other groups for analogous η^5 -monocyclopentadienyl- or indenyl-metal complexes [135, 136]. For aryl nitrile complexes, the hyperpolarizability was demonstrated to increase in the series $\text{Co(III)} < \text{Ni(II)} < \text{Ru(II)} < \text{Fe(II)}$, with about a three-fold increase from Ru(II) to Fe(II) [136]. Yet the Fe(II)–arylnitrile complexes were still less NLO efficient than their ruthenium–arylacetylide counterparts, indicating the superiority of the acetylide bridge [129, 136]. In addition, heterobimetallic complexes with a ruthenium bis(triphenylphosphine) (indenyl)acetylide donor were reported that exhibit the largest hyperpolarizabilities recorded to date for bimetallic systems [7, 135, 137]. The combination of the ruthenium–acetylide donor with the pyridyl-metal-

pentacarbonyl acceptor delivered larger NLO properties than their metallocene derivatives (vide supra). This is in agreement with the better electron donor properties experienced for the metal–acetylide group [7]. Recently, octopolar alkynylruthenium complexes were synthesized to reduce the nonlinearity–transparency trade-off [138]. The octopolar symmetry was shown to enhance the molecular hyperpolarizability without any loss in transparency.

Another dipolar *in-plane* route toward NLO chromophores involves donor/acceptor-substituted *trans*-tetraamineruthenium(II) complexes $\text{trans}[\text{Ru}(\text{NH}_3)_4(\text{L}^{\text{A}})(\text{L}^{\text{D}})]^{n+}$ (L^{A} = an acceptor-substituted pyridine ligand; L^{D} = an N-donor ligand) that show coplanarity of the axial ligands which can allow π – π coupling through the polarizable ruthenium center. The π – π coupling was suggested to induce large hyperpolarizabilities that can easily be modified by an appropriate choice of substituents. Indeed, the studies of Coe et al. revealed large, tunable hyperpolarizabilities $((10\text{--}410) \times 10^{-30}$ esu) [139–143]. However, no coupling between L^{A} and L^{D} was observed. Moreover, the electrochemical and NLO properties strongly suggest that the role of the donor ligand is restricted to the fine-tuning of the electronic properties of the metal, which remains the effective donor. Furthermore, the effect of the oxidation state of the metal upon the molecular optical nonlinearity was addressed. Chemical oxidation of the metal was proven to be an excellent tool to reversibly switch the molecular first hyperpolarizabilities of the *trans*-substituted ruthenium complexes [142]. Modulation “after synthesis” of the molecular hyperpolarizability was also performed for octopolar ruthenium(II) trisbipyridine. Both electrochemical and optical switching ($\text{Ru(II)} \rightarrow \text{Ru(III)}$) led to an apparent decrease in the SHG signal as a result of the reduced electron donor strength of Ru(III) [144–146].

Functionalization of the bipyridine ligand (enlarging the conjugation) proved an excellent tool for working toward ruthenium(II)trisbipyridine complexes with substantially enhanced nonlinearities [147]. Although the initially reported hyperpolarizabilities, obtained by HRS, were overestimated due to luminescence contributions, the fluorescence-free hyperpolarizabilities $((800\text{--}1000) \times 10^{-30}$ esu) are still impressive [127, 148].

Furthermore, the second-order NLO properties of metal–Schiff base complexes have been investigated [149–152]. For (*N,N'*-disalicylidene-1,2-phenylenediaminato)- M(II) ($\text{M} = \text{Co}, \text{Ni}, \text{Cu}$) the hyperpolarizability as measured with EFISHG, as well as the calculated values, increased on going from the closed shell d^8 Ni(II) to the open-shell d^9 Cu(II) and d^7 Co(II) analogs [149]. Improved accessibility of lower-lying excited states in the case of the open-shell complex was suggested to account for the larger hyperpolarizability. As for metallocenes, the two-level model does not hold for open-shell complexes, in contrast to the closed-shell ones. However, results on a similar metal–Schiff base complex present a similar hyperpolarizability for both the open-shell Cu(II) and the closed-shell Ni(II) complex, and thus undermine the previous findings [151].

For a series of square planar metal(diimine)(dithiolate) complexes, the relationship between the optical CT properties and the molecular hyperpolarizability has been studied. Compared with the Pd(II) and Ni(II) derivatives, the Pt(II) metal ion provides the largest NLO response, resulting from its low transition energy and

greater oscillator strength [153]. Furthermore, the HOMO (LUMO) is shown to be centered on the dithiolate (diimine) ligand.

The largest hyperpolarizability reported to date for a metallo-organic compound is that of the push–pull 5-{{4'-(dimethylamino)phenyl}ethynyl}-15-[(4''-nitrophenyl)-ethynyl]-10,20-diphenylporphinato]Zn(II) complex [154, 155]. Note, however, that compared with acetylenyl-bridged D–porphyrin–A systems, phenyl-bridged metalloporphyrins exhibit rather small hyperpolarizabilities [155, 156]. In the absence of the acetylenyl bridge, the electronic communication between donor and acceptor through the porphyrin bridge is strongly reduced as a consequence of the dihedral angle between the phenyl rings and the porphyrin base. In fact, it is this electronic communication that plays an important role, as evidenced by transient spectroscopy as well as by Stark spectroscopy [157, 158]. The latter reveals that the large dipole moment difference between ground and excited states, required by the two-level model for good hyperpolarizabilities, does originate from the communication between donor and acceptor through the porphyrin bridge.

Silicon can be incorporated as a donor, bridge, or even as an acceptor into an organic system [159–161]. Studies report rather moderate quadratic hyperpolarizabilities, the largest efficiency being found for the silicon donor. The main advantage of these systems compared with other metallic complexes is their transparency in the visible region.

In general, the addition of the metal leads to an increased hyperpolarizability compared with that of the free ligand. However, like organic compounds, metallo-organic complexes suffer from the nonlinearity–transparency trade-off. As mentioned, the MLCT/LMCT transitions that are responsible for the hyperpolarizabilities are very strong and lie in the visible region, especially in the case of the most promising metallo-organic complexes such as rutheniumtris(bipyridine), ruthenium- σ -arylacetylide or zincarylacetylporphyrins.

8.4 Macroscopic Nonlinearities

A strict requirement for induction of second-order nonlinear optical effects in a macroscopic material is the absence of centrosymmetry. Macroscopic non-centrosymmetry has proven to be much more difficult to achieve than molecular non-centrosymmetry. It can be achieved by, for example, non-centrosymmetric crystallization, electric-field or optical poling, self-assembly or Langmuir–Blodgett film formation [5, 6, 162]. One important requirement for these materials, in order to be useful for applications, is high nonlinearity. For example, it has been shown that for frequency-doubling applications a material should have a second-order susceptibility on the order of 60 pm V^{-1} ($1 \text{ pm V}^{-1} = 3.387 \times 10^{-9} \text{ esu}$). For electro-optic applications, an electro-optic coefficient of at least 10 pm V^{-1} is required [91]. Other issues that are important from an applications point of view are thermal, (photo)chemical, and mechanical stability, and a high transparency at the operating wavelength of the device.

For electro-optic applications, the most promising method to achieve non-centrosymmetry is probably electric-field poling of polymers containing nonlinear optical chromophores (NLO polymers) [91]. Such materials are inexpensive, easy to fabricate, have good film-forming properties for making waveguide structures, and are compatible with existing semiconductor technologies. It has already been demonstrated that high-performance electro-optic devices based on poled polymers can be made. For example, 113 GHz electro-optic modulation with low drive voltages has been demonstrated from a polymer-based phase modulator [163]. On the other hand, the development of polymeric materials for frequency conversion processes has been less successful, in particular because of low nonlinearities, absorption losses, and phase-matching problems.

To produce a non-centrosymmetric polymer film, an NLO polymer is spin-coated onto an ITO (indium tin oxide)-coated substrate. The films are carefully dried under vacuum at elevated temperatures, yielding thin films (micrometer thickness) of excellent optical quality. Subsequently, the films are heated to their glass transition temperature (T_g) where they become rubbery. A strong applied static electric field (by corona discharge or contact poling) can then orient the chromophores in the matrix to impose a non-centrosymmetric $C_{\infty v}$ symmetry on the polymer film. The chromophores in the films are oriented by coupling of their static dipole moment with the poling field. Then the film is cooled to room temperature in the presence of the electric field to freeze in the alignment of the NLO molecules. Now the field can be safely removed since the orientation of the chromophores is strongly hindered below T_g . The symmetry of the poled film is $C_{\infty v}$ and its second-order nonlinearity can be described by two independent (under the assumption of Kleinman permutation symmetry) susceptibility components zzz and zxx (z -axis perpendicular to the film plane and x -axis in the plane of the film) [91]. However, note that in order to design electro-optic (EO) devices, thin film preparation and poling are not the only issues that need to be considered. A careful electrode design, the identification of suitable buffer or cladding layers and channel waveguide patterning are equally crucial in the design strategy of a practical modulator [162].

NLO polymers are designed by incorporating nonlinear chromophores into a polymer matrix. The simplest approach is the use of polymer solutions, so-called guest–host systems, in which the nonlinear chromophore is dissolved in a compatible polymer matrix. Unfortunately, the solubility of guest molecules in a polymer matrix is usually low, which limits the magnitude of the NLO response. This problem is solved by attaching the chromophores covalently to the polymer backbone (side chain polymers) or by incorporating them into the backbone of the polymer (main chain polymers).

One of the major problems associated with poled polymer films is their inherent thermodynamic instability: the chromophores in the polymer matrix tend to relax with time, eventually leading to a centrosymmetric system. Methods to circumvent this problem include crosslinking and the use of polymers with very high glass transition temperatures.

Unfortunately, electric-field poling is not applicable to octopolar systems, because of the absence of a dipole moment. However, the recently developed all-optical poling might be useful in obtaining the required non-centrosymmetry. All-optical

poling is based on the fact that combinations of certain light fields exhibit polarity. For example, the coherent superposition of a field at frequency $\omega[E(\omega)]$ and one at frequency $2\omega[E(2\omega)]$ leads to a time-averaged cubic interference term $\langle E^3 \rangle$ where $E = E(\omega) + E(2\omega)$. Furthermore, its irreducible tensor decomposition has a component with octopolar symmetry. Therefore coupling of this field with a molecule is permitted even in the absence of a dipole moment [162]. Recently, the octopolar molecule ethyl violet was oriented in a sol-gel matrix by all-optical poling. The sample had a second-order susceptibility with octopolar symmetry of 0.6 pm V^{-1} (measured at 1064 nm) [164].

A second approach to achieve macroscopic non-centrosymmetry is the formation of crystals [6]. In principle, single crystals are very attractive NLO materials (both for frequency conversion and the electro-optic effect) because of their superior long-term stability and very high density of active components. However, the fabrication of single crystals of good quality is often a very tedious and time-consuming procedure and the fabrication of waveguide structures might be difficult. In addition, only a few highly nonlinear chromophores have been incorporated into a useful crystalline material over the past few years. The reason is that most of the highly nonlinear organic molecules crystallize centrosymmetrically. In addition, the orientation of the chromophores in the crystal lattice needs to be optimized in order to obtain a useful material. Several strategies have been used to induce non-centrosymmetric crystallization. For example, the use of chiral molecules automatically introduces non-centrosymmetry into the crystal but does not necessarily lead to an optimum arrangement of the nonlinear optical chromophores in the crystal lattice [165]. A new strategy for crystal engineering in which different materials are mixed takes advantage of specific intermolecular interactions (such as hydrogen bonds) to favor non-centrosymmetric packing. For example, co-crystals of a merocyanine dye and methyl 2,4-dihydroxybenzoate, in which the merocyanine and the dihydroxybenzoate are linked by a short hydrogen bond, were shown to be highly efficient materials for electro-optic applications (electro-optic coefficient 30 pm V^{-1} at 1535 nm) [166]. Recently, Hulliger et al. introduced NLO chromophores in the channels of perhydrotriphenylene crystals, leading to highly efficient SHG inclusion materials [167].

Another approach to organizing molecules non-centrosymmetrically has been to incorporate NLO chromophores into Langmuir-Blodgett films [6]. The advantage of this approach is the much better chromophore alignment and chromophore density. A major drawback is the often poor optical quality due to microdomain formation and the poor temporal stability and fragility. A related approach that is based on covalent self-assembly techniques to make artificial superlattices solves the problem of stability and fragility by covalently linking different layers of the superlattice [168]. On the other hand, since each layer of the superlattice involves a chemical reaction, the question remains of whether sufficiently thick layers (of micrometer thickness) with good optical quality can be obtained. Both approaches have shown some encouraging results, leading to relatively stable films with useful nonlinearities [168–172].

Chiral materials are also potentially interesting for applications in second-order nonlinear optics. For example, chirality has been extensively used to prevent cen-

trosymmetric crystallization [165]. In addition, since chiral materials are inherently non-centrosymmetric, even highly symmetric media (such as isotropic solutions of chiral molecules) are non-centrosymmetric and therefore possess a non-vanishing second-order susceptibility. For example, sum-frequency generation from a sugar solution was already observed in the early days of nonlinear optics [173]. Although this particular process cannot be phase-matched, the result is significant because the thermodynamic stability of the material was not sacrificed. However, second-harmonic generation from isotropic chiral solutions is forbidden.

Recently, it was theoretically shown, on the basis of standard density-matrix formalism of nonlinear optics, that chiral isotropic media can possess an electro-optic response [174]. Such materials would be inherently stable and could therefore be extremely useful for the development of electro-optic devices. Contrary to usual electro-optic materials, index (absorption) modulation in such media is due to the imaginary (real) part of the electro-optic susceptibility. The response relies on the damping of the material response.

Imaging and Information

1 Electron Transfer Processes in Silver Halide Photography

John R. Fyson, Peter J. Twist, and Ian R. Gould

1.1 Introduction

Silver halide color photography represents one of the most technologically complex applications of electron transfer chemistry in use today. The photosensitive component of a typical color negative film consists of 10–15 layers with a total thickness of only ca. 20 μm , each with different optical properties and chemical functions. Modern films typically contain over 100 different organic compounds and several million silver halide microcrystals per square millimeter. The light-induced image capture events, and the subsequent image development processes involve a variety of homogeneous and heterogeneous photochemical and thermal electron transfer reactions. In the image capture step, light which is absorbed by sensitizing dyes adsorbed onto the surface of silver halide microcrystals results in transfer of electrons to silver halide. Transfer of only a small number of electrons results in the formation of a small, stable speck of metallic silver. Otherwise undetectable by conventional analytical techniques, this silver speck serves as a latent image which catalyzes the formation of a visible dye image in the development step. The dye-forming processes involve oxidative coupling reactions with transfer of four electrons to the silver halide for each dye molecule formed. Importantly, a single latent image of a few silver atoms in a crystal can catalyze the formation of millions of dye molecules. It is this huge amplification factor that makes silver halide materials unique in imaging applications. Subsequent to development, the metallic silver formed in the development process is removed in a bleaching step by electron transfer to an oxidizing agent to reform silver ions, which are then dissolved out of the film in the fixing step. Thus, electron transfer reactions are involved in the entire image forming process.

A description of the entire photographic process is clearly beyond the scope of this article, which concentrates on the chemical and physical aspects of the significant electron transfer reactions involved the three fundamental steps described above, i.e., image capture, development, and bleaching. Other aspects of photo-

graphic chemistry and physics, i.e., fixing and washing, are included here only when necessary to provide the proper context. The important electron transfer chemistry involved in image development and the bleaching process is described first, followed by the more physical aspects of the spectral sensitization processes involved in the primary image capture events.

1.2 Developers

1.2.1 Introduction

It is estimated that the amount of silver required in the latent image needed to produce all the amateur photographic images captured in 1998 only amounted to less than 10 g. The energy used in creating this silver from silver halide is perhaps as little as 10 kJ. This is spread over perhaps 10^{12} images. This small amount of silver which constitutes the latent image has to be amplified to render it visible, to be seen by the eye, by a scanner, or by a piece of photographic paper in a printer or enlarger. The property of the developer is to detect this latent image and to amplify it, ideally in a fashion that is related directly to the exposure.

The presence of the latent image in exposed silver halide was first observed by Daguerre [1], who discovered that hidden images on exposed photographic plates were rendered visible when kept inadvertently in a cupboard with bottles of mercury. He attributed this effect to the mercury revealing this hidden image by amalgamating with it. This process was improved and became popular as Daguerreotypes. At the same time Fox Talbot was experimenting with silver salts adsorbed to paper. He heard that Reade had observed that a mixture of gallic acid, 3,4,5-trihydroxybenzoic acid, and silver nitrate turned black in sunlight [2]. Talbot found that if he included the reducing agent gallic acid in the paper he no longer required the image to become visible before processing it [3]. It could be rendered visible by further treatment with a solution of gallic acid and silver nitrate. This mixture was probably the first photographic developer in the sense that we know it today, with properties of a physical developer. He also discovered that the image would appear spontaneously if left in the dark for a few minutes. Thus he had been able to make the first incorporated developer material. Images produced in this way were known as Calotypes. Other reducing agents that were tried include pyrogallol (1,2,3-trihydroxybenzene) and transition metal complexes, especially those of iron(II) [4]. The first observations that development might involve electrical activity appear to have been made by Terry [5]. He described development as being the result of galvanic action. One might dispute the logic of his hypothesis but it fits with more modern thinking. He also described the use of a developer of mixed iron(II) and iron(III) complexes [4] to get the best image, or discrimination as we would now call it. It was necessary to have a developing agent of reducing power that was sufficient to develop silver at the latent image site, but not too powerful so as to render all the image black. Cramp and Hillson [6] used a similar technique to examine the excess energy of the latent image some 130 years later! In 1880 Abney

[7] reported a new developer, hydroquinone, that had been used to develop collodion silver bromide plate. This was originally a very expensive natural product [8], but a synthetic process reduced its cost and it became a popular developing agent used with sulfite [9]. It was also discovered that *p*-aminophenols [10] and naphthols [11] would act as developers. These had different characteristics from the hydroquinone developers. The image would appear immediately but did not reach such a high density as with hydroquinone. When the two types of developer were mixed, the image appeared rapidly and good image tones were formed [12]. This was the first “superadditive” developer.

p-Phenylenediamines could also be used as developers. Fischer [13] discovered that the oxidation product of the development reaction would react readily with color formers, now known as couplers, to form various colored images. He also suggested a three-color process by incorporating different couplers to form different colors in separated layers containing silver sensitized to different wavelengths of light. This reaction was the basis of the chromogenic color process. The technology of retaining the couplers in the emulsion was not available and it was the Kodachrome process, invented by Mannes and Godowsky [14], that became the first color film process to rely on different couplers, but these were added in three separate developers. Color-forming couplers were found that could be coated and did not diffuse out of the photographic layer, and a practical reversal system was launched in 1936. This was quickly followed by negative working films and papers.

A typical color process in use today (see Table 1), using this chromogenic method of forming color, consists of a number of steps. The developer forms the color and simultaneously generates unwanted silver. This is removed in the bleach. Silver halide retained in the film is then removed in the fixer. The washes remove unwanted residual chemicals in the film and prevent contamination of one bath by another.

1.2.2 Chemical Development

Changes in silver halide caused by development

The exposure of a light-sensitive photographic material based on silver halide causes microscopic changes to occur in the silver halide crystal. These changes result in

Table 1. A typical color process [15].

Step	Time [s]	Temperature [°C]
Develop	195	37.8
Bleach	260	35–41
Wash	65	24–41
Fix	260	35–41
Wash	195	24–41
Stabilise	65	24–41
Dry	as required	as required

Figure 1. Idealized development of exposed and unexposed silver halide. In practice a small amount of development occurs, even in the unexposed silver halide.

what is called a latent image (Figure 1). The latent image consists of a few to several hundred atoms of silver metal. The latent image is too small to be visible and chemical development is the term used to describe the process of rendering an exposed image visible. The minimum size of the latent image that is able to initiate development is four atoms of silver and two atoms of gold [16]. Gold can be incorporated into the latent image because it is used to chemically sensitize silver halide in order to improve its light sensitivity. Development reduces solid silver halide to silver metal with the release of halide ions and the amplification factor involved in this process is large, at about 10^7 – 10^9 . A modern ISO 400 speed silver halide emulsion has an average grain volume of about $0.5 \mu\text{m}^3$ (A. Codling, private communication), and silver bromide has a density of 6.473 [17] and a molecular weight of 187.78; from this the average number of molecules of silver bromide per grain can be calculated at 10.24×10^9 . If the latent image contained four atoms the amplification factor for complete development of the average grain to metallic silver is therefore about 2.5×10^9 . This number is higher than that for most normal exposures when the latent image will contain many more silver atoms. In addition, silver halide grains are only partially developed in high-speed color negative films.

Developed silver is usually filamentary in nature and often occupies about the same volume as the original silver halide grain but as a complex tangle of silver filaments (Figure 2).

Chemical development follows two stages [18], the first being the relatively slow initiation period during which visible silver is not formed but in which the latent image grows spherically before gross reduction of the silver halide commences. This stage has also been called the induction period, although another definition of in-

Figure 2. Photomicrograph of silver halide grains and developed silver.

duction period refers to it as the period, over which the rate of growth of image density increases. The second stage of chemical development, the continuation stage, involves the reduction of the entire silver halide grain to silver. It is during this stage that filamentary silver is formed. Increase in exposure mainly causes an increase in the number of developed silver grains with a relatively small change in the degree of development per grain, although the number and size of latent image sites can also increase. Some silver halide emulsions are designed to be partially developed: in this case only part of a given silver halide grain is reduced to silver. This process is encouraged in color negative films by the use of special compounds, called development inhibitor releasers, incorporated into photographic layers which inhibit the development process in order to improve the graininess of the image.

The response of a photographic material to exposure and development is represented by means of a density vs. relative log exposure (D vs. $\log E$), or H and D curve after Hurter and Driffield [19]. A typical curve for black-and-white development is shown in Figure 3.

The rate of development can be represented by a development-time plot; the shape of this curve can vary depending on the type of developer used, as shown in Figure 4. In this plot the main developing ion has a charge of 0, 1-, 2-, or 3-; in order to explain the curve shape for different developing agents James [20] proposed the charge-barrier theory, according to which a negative charge barrier caused by the adsorption of halide ions is formed at the silver halide surface and represents an obstacle through which developing agent ions must pass to cause development. Uncharged developing agents are not affected and develop from the start, whereas

Figure 3. A typical development vs. relative log exposure curve or D vs. $\log E$ curve.

with increasing charge on the developing agent ion there is an increasing induction period. This is due to the lower concentration of negative developing agent ions close to the negatively charged silver halide surface, which lowers the development rate in the early stages. As development proceeds, silver halide is replaced by developed silver and the charge barrier is reduced, enabling the development to accelerate. In general the curve for zero-charged agents, when treated in terms of developed silver rather than silver density, shows the expected behavior for autocatalytic development based on the increasing surface area of the developed silver. Hillson [21] has treated this concept from an electrochemical point of view and concludes that a decrease in the charge barrier is not necessary in order to explain the kinetics.

The rate of development is related to the concentration of developing agent in solution and the rate equation takes the form

$$d[\text{Ag}]/dt = k[C]^n \quad (1)$$

where n is often fractional but usually between 1 and 0.5. The rate can also depend on the amount of silver reduced, as found by Fyson and Levenson [22], who observed two types of relationship involving silver, depending on which developing agent was

Figure 4. Density vs. relative time of development for differently charged developing agents [20]. The charges are shown on the curves.

used. In Eq. (2),

$$d[\text{Ag}]/dt \propto [\text{Ag}]^{2/3}(1 - [\text{Ag}]) \quad (2)$$

where $[\text{Ag}]$ is the amount of silver reduced, the first term indicates dependence on the surface area of the growing silver image and the second term indicates dependence on the remaining unreduced silver halide. The second type of relationship was Eq. (3),

$$d[\text{Ag}]/dt \propto (1 - [\text{Ag}]) \quad (3)$$

in which the rate depends on the remaining silver halide.

If the development rate by negatively charged developing agent ions is monitored until all the silver halide is reduced, it follows a typical S-shaped curve that has been interpreted as a consequence of autocatalysis caused by the increasing surface area of the developed silver. An alternative interpretation by Gavrik [23] holds that this autocatalysis is a consequence of simpler kinetics and that development is better represented by simple relations where developed silver mass is proportional to development time with an initial induction period and a final exhaustion period when all the silver halide has been reduced. Levenson [24], however, has reaffirmed the autocatalytic view.

Physical development is another type of development, in which soluble and usually complexed silver ion is reduced from solution onto nuclei, which can be latent image nuclei, other suitable nuclei, or silver produced by chemical development. "Chemical development" and "physical development" are traditional terms derived

from early in the understanding of photographic processes, yet both are processes of chemical reduction or electron transfer.

Developing solutions

The essential ingredient in a photographic developer solution is the developing agent, which is a special type of reducing agent capable of reducing only those silver halide crystals that bear a latent image and not those which do not have a latent image (see Figure 1). This is the ideal case and even the most carefully chosen developing agents will cause the reduction of some crystals of unexposed silver halide, giving what is colloquially referred to as fog. Fog is kept to a minimum by very closely controlled precipitation of the silver halide crystals to give a photographic emulsion which is actually a dispersion of silver halide, usually in gelatin solution. The term "photographic emulsion" is a misnomer since strictly speaking it is a dispersion, but the term emulsion is universally used to describe it. In addition the developer solution is carefully designed to minimize fog and often contains restrainers and antifoggants which help in this regard. A black-and-white film developer composition is given in Table 2 and a color film developer composition in Table 3.

Table 2. Example of a black-and-white developer.

Function	Component	Concentration
pH buffer	Na ₂ CO ₃	37.5 g
Restrainer	KBr	2.0 g L ⁻¹
Antifoggant	BTAZ ^a	0.15 g L ⁻¹
Antioxidant	Na ₂ SO ₃	75 g L ⁻¹
Primary developing agent	phenidone ^b	0.25 g L ⁻¹
Secondary developing agent	hydroquinone	8 g L ⁻¹
pH		9.5

^a 5-methylbenzotriazole, ^b 1-phenyl-3-pyrazolidinone.

Table 3. Example of a color developer.

Function	Component	Concentration
Anti-calcium agent	DTPA · Na ₅ (40 %) ^a	6.5 mL L ⁻¹
pH buffer	K ₂ CO ₃	37.5 g L ⁻¹
Restrainer	NaBr	1.3 g L ⁻¹
Antioxidant	HAS ^b	2.0 g L ⁻¹
Antioxidant	Na ₂ SO ₃	4.25 g L ⁻¹
Color developing agent	CD4 ^c	4.5 g L ⁻¹
pH	KOH	to pH 10.0

^a diethylenetriaminepentaacetic acid sodium salt, ^b hydroxylamine sulfate, ^c 4-amino-3-methyl-*N*-ethyl-*N*-(hydroxyethyl)aniline sulfate.

Thermodynamically, developing agents are capable of reducing all the silver halide crystals in a photographic emulsion to silver metal, and the primary function of the silver latent image is to act as a catalyst to accelerate the development of those crystals bearing the latent image relative to those which do not. Electron transfer from the developing agent to silver halide is slow whereas electron transfer from the developing agent to the latent image is fast. Thus photographic development of the latent image is a kinetically controlled reaction and discrimination of the photographic image depends on this reaction being faster than the development of unexposed silver halide. The main reaction involved in development by a one-electron developing agent is generally described by Eq. (4)

where Dev is the reduced form of the developing agent and Dox is the oxidized form. Hydrogen ions are one of the products of the reaction when organic developing agents are used. Organic developing agents are thus involved in both electron transfer and proton transfer reactions and the development reaction is therefore a pH-dependent redox process.

This overall reaction can be considered as two electrochemical half-cell reactions each involving the transfer of one electron (Eqs. (5) and (6)).

Each of these half-cell reactions has a redox potential, E_{Ag} for reaction (5) and E_{Dev} for reaction (6), which can be measured experimentally at an electrode in an electrochemical cell relative to a reference such as the hydrogen or calomel electrode. In order for reduction of silver ion to proceed, the difference $E_{\text{Ag}} - E_{\text{Dev}}$ must be positive, whereas if it is negative silver dissolution or bleaching reaction occurs. In addition it has been found that the magnitude of the difference $E_{\text{Ag}} - E_{\text{Dev}}$ needs to be above a value referred to as the critical potential, for significant development to be observed. Reinders found that the critical potential was about 90 mV, below which no development was observed [25]. A range of critical potential values from about 50 to 160 mV has been found, depending on developer composition [26]. In contrast to these values for the development of silver halide, no critical potential was observed by Pontius et al. [27] for physical development on colloidal or latent image nuclei. It was observed, however, that as $E_{\text{Ag}} - E_{\text{Dev}}$ increased, so did the rate of physical development. This is discussed further in the next section. The electrochemical thermodynamics of the half-cell reactions is described by the Nernst equation; for the silver half-cell it is Eq. (7),

$$E_{\text{Ag}} = E_{\text{Ag}}^\circ + \frac{RT}{F} \ln \frac{[\text{Ag}^+]}{[\text{Ag}]} \quad (7)$$

where E_{Ag}° is the standard silver potential measured at 25°C and unit activity, $[\text{Ag}^+] = 1.0 \text{ M}$, the activity of solid silver $[\text{Ag}]$ is defined as 1.0 and E_{Ag} is the potential at other Ag^+ ion concentrations and other temperatures. The silver ion concentration depends on the type of silver halide that is being reduced and is affected by the free halide concentration at the development site. The solubility product of the silver halide K_{sp} is given by Eq. (8), which when substituted in Eq. (7) gives Eq. (9).

$$K_{\text{sp}} = [\text{Ag}^+][\text{Br}^-] \quad (8)$$

$$E_{\text{Ag}} = E_{\text{Ag}}^\circ + \frac{RT}{F} \ln \left(\frac{K_{\text{sp}}}{[\text{Br}^-]} \right) \quad (9)$$

At 25°C this becomes Eq. (10).

$$E_{\text{Ag}} = E_{\text{Ag}}^\circ + 0.0591 \log_{10} \left(\frac{K_{\text{sp}}}{[\text{Br}^-]} \right) \quad (10)$$

The solubility products K_{sp} are $\text{AgCl} = 1.56 \times 10^{-10}$, $\text{AgBr} = 7.7 \times 10^{-13}$, and AgI , 1.5×10^{-16} [17], and $E_{\text{Ag}}^\circ = 799 \text{ mV}$ (NHE). In color developer solutions a common level of sodium chloride or bromide is about $1\text{--}2 \text{ g L}^{-1}$ or about 10^{-2} M . Under these conditions the silver potentials (NHE) for the different halides are $\text{AgCl} = 338 \text{ mV}$, $\text{AgBr} = 202 \text{ mV}$, and $\text{AgI} = -17 \text{ mV}$. The silver ion concentration can also be influenced by the presence of silver ion ligands. A silver ion complexing agent will lower the silver ion concentration and so lower the silver potential.

The developer half-cell potential is given by Eq. (11).

$$E_{\text{Dev}} = E_{\text{Dev}}^\circ + \frac{RT}{F} \ln \frac{[\text{H}^+][\text{Dox}]}{[\text{Dev}]} \quad (11)$$

The driving force $E_{\text{Ag}} - E_{\text{Dev}}$ for the development reaction with a given developing agent becomes less on going from silver chloride to silver bromide to silver iodide, and so development is more difficult and the development rate tends to be lower down this series. A more formal discussion of the dependence of development rate on overpotential is given in the section entitled "Development mechanism", below.

In practice many developing agents, such as *p*-phenylenediamines, *p*-aminophenols and hydroquinones, are two-electron reducing agents. In general *p*-phenylenediamine developing agents have one nitrogen substituted with alkyl or alkoxy groups and the like, in order to influence properties such as solubility, reactivity, and stability of dyes formed by coupling (see Section 1.2.3). The reaction of a typical *p*-phenylenediamine (PPD) with silver halide is shown in Eq. (12).

The semiquinone (SH^+) is unstable and can lose another electron to form the quinonediimine QDI (Eq. (13)) [28].

In addition the semiquinone (SH^+) can undergo a reversible dismutation [29], to generate PPD and QDI (Eq. (14)).

This equilibrium is very rapidly established and, for example, in the case of *N,N*-diethyl-*p*-phenylenediamine (CD1) the rate constant for the forward reaction is $k_f = 2.0 \times 10^6 \text{ L mol}^{-1} \text{ s}^{-1}$ and the rate constant for the backward reaction is $k_b = 6.3 \times 10^{11} \text{ L}^2 \text{ mol}^{-2} \text{ s}^{-1}$ [29c].

The oxidation potentials E_1 and E_2 for transfer of the first and second electrons in the development of silver halide have been estimated [28] for several developing agents: the rate of development correlates better with E_1 than with E_2 , suggesting that the oxidation to the semiquinone is the rate-determining step in development.

Figure 5. Typical *p*-phenylenediamine color developing agents, known as CD1–CD4 in the photographic industry.

The quinonediimine (QDI) is an important species in color development since it is this that forms dye on reaction with a coupler molecule and transforms a black-and-white image into color (see Section 1.2.3).

Typical *p*-phenylenediamine color developing agents are shown in Figure 5.

Hydroquinone (H₂Q) is another developing agent and is commonly used in black-and-white processes, usually in conjunction with an auxiliary developing agent such as Metol (*N*-methyl-*p*-aminophenol), which is also called Elon, or Phenidone (1-phenylpyrazolidin-3-one) (see Figure 6), a heterocyclic agent (see Section 8.2.5). The overall reaction of hydroquinone with silver halide is shown in Eq. (15). In fact hydroquinone undergoes two sequential one-electron transfer steps, with an intermediate semiquinone (S[•]) and with *p*-benzoquinone (Q) as the final product.

The half-cell reaction for hydroquinone is given in Eq. (16),

Figure 6. Half-wave potentials for the oxidation of three hydroquinones as a function of pH [28–30].

where Q is *p*-benzoquinone and H₂Q is hydroquinone. In this half-cell reaction two electrons and two protons are transferred. The Nernst equation is Eq. (17).

$$E_{\text{HQ}} = E_{\text{HQ}}^{\circ} + \frac{RT}{2F} \ln \frac{[\text{H}^+]^2[\text{Q}]}{[\text{H}_2\text{Q}]} \quad (17)$$

The potential for equal amounts of oxidized and reduced forms of the developing agent is closely related to the polarographic half-wave potential and differs only by a term containing the ratio of the diffusion coefficients for the oxidized (D_{Ox}) and reduced forms (D_{R}) [30].

$$E_{1/2} = E_m + \frac{RT}{nF} \ln \left(\frac{D_r}{D_{ox}} \right) \quad (18)$$

where $E_{1/2}$ is the polarographic half-wave potential and E_m is the median potential of the redox system when the oxidized and reduced forms are at equal concentration, which would be obtained from a potentiometric titration. pH vs. potential diagrams are a convenient way to examine the redox properties of developing agents, as shown in Figure 6 for some hydroquinones and Figure 7 for some *p*-phenylenediamines.

Although the equilibrium potentials for many developing agents can be calculated from the Nernst equation for a given pH, the potential values that apply in practical developer solutions are less well defined. In practice the reactions occurring in development are not at equilibrium, the reaction is almost all in one direction to form silver metal and oxidized developing agent, which is removed quickly from the reaction site before a significant amount of the reverse reaction can occur. This means that there is usually a large excess of the reduced form of the developing agent and a fleeting and indeterminate amount of the oxidized form. It is clear from some of the potential pH diagrams and from the silver ion potentials for the different silver halides that development would not occur over most of the pH range unless the reduced form of the developing agent was in considerable excess. The ratio of oxidized to unoxidized forms has been estimated to be about 10^{-4} , which is equivalent to a potential that is lower by about 120–240 mV than the half-wave potential. This is because the removal of the oxidized form of the developing agent by diffusion out of coated layers is assisted by good agitation and by several reactions which the oxidized developing agent can undergo, as outlined below for color developing agents such as *p*-phenylenediamines.

In all practical color developer solutions an antioxidant is present to help preserve the color developing agent against aerial oxidation. Aerial oxidation is slow, of the order of hours to days, compared with the development reaction, which is of the order of seconds to minutes. The antioxidant converts oxidized developing agent back to its reduced form, thus regenerating it. This reaction is again relatively slow compared with the development reaction and subsequent coupling to form dye (see Section 1.2.3), so there is only a small amount of unwanted loss of oxidized developing agent. The most common antioxidants for color developer solutions are based on hydroxylamine and its derivatives. The reactions involved are represented by Eqs. (19) and (20) [31],

where PPD is a *p*-phenylene diamine and QDI is a quinonediimine. This is one suggested stoichiometry and the reaction is probably more complicated since oxidation of hydroxylamine can give several other products such as nitrous oxide and hyponitrite. Thus the level of oxidized developer present in a practical developer is

Figure 7. Left-hand curve: Half-wave potential for oxidation of *N,N*-dimethyl-*p*-phenylenediamine as a function of pH Right-hand curve: Half-wave potential for oxidation of *p*-phenylenediamine as a function of pH [30].

low, and not much above zero. The rate of development is not affected by moderate exposure to the air, indicating little buildup of oxidized developing agent.

Sulfite ion has been used as a preservative in photographic developer solutions since 1882 [31]. It is present at a relatively low level in many modern color developers and can act as a preservative by removing oxygen from solution and also by removing developer oxidation products as shown in Eq. (21).

These reactions involve proton and electron transfer and kinetic data suggest that the mechanism involves a protonated intermediate followed by base-catalyzed deprotonation of the ring [32]. In black-and-white developers the amount of sulfite present is usually very high at about 60 g L⁻¹ of sodium sulfite (0.5 M), and almost all the oxidized developer formed is immediately removed from the reaction site. (At low sulfite levels the effects of accumulated oxidation products can have a significant effect on the development rate, particularly for hydroquinone developers; see the section on "Lith development"). In the case of hydroquinone the reaction with sulfite is similar to that of *p*-phenylenediamine (Eq. (22)).

This reaction involves both proton and electron transfer and rapidly removes the oxidation product of hydroquinone development and generates the sulfonated form of the developing agent. The sulfonated hydroquinone is also a developing agent but has a potential about 70 mV higher at pH 10 and is therefore less active than hydroquinone. In addition to removing oxidized developing agent, sulfonation also raises the pH of the solution, which can be of practical importance.

The reactions of quinonediimine are reviewed by Brown [33]. The quinonediimine (QDI) is susceptible to hydroxide ion attack and forms the quinonemonoimine (QMI) according to the mechanism shown in Eq. (23) [34].

Azo dyes can be formed by the self-condensation of a quinonediimine and a *p*-phenylenediamine [35]. The rate dependence has been found to be given by Eq. (24),

$$\frac{d[\text{Azo}]}{dt} = k_1[\text{PPD}][\text{QDI}^+][\text{OH}^-] \quad (24)$$

which can be interpreted by the mechanism shown in Scheme 1.

Coupling of oxidized developing agent with couplers incorporated in the sensitized material lowers the level of oxidized developer (see Section 1.2.3).

Scheme 1. Suggested mechanism for formation of azo dye from a quinonediimine and a *p*-phenylenediamine. RDS, rate determining step.

Phenidone: $R^1 = R^2 = R^3 = H$
 Dimezone: $R^1 = R^2 = CH_3$; $R^3 = H$
 MOP: $R^1 = CH_3$; $R^2 = OCH_3$; $R^3 = H$

Figure 8. Pyrazolidone developing agents.

Coated photographic layers are immersed in developer solutions and rely on the diffusion of active components into and out of the layer. Since chemical development occurs at local sites within the layer, agitation helps to remove oxidized developing agent into the effectively infinite sink of the bulk developer solution, and to replace it with the reduced form. In addition agitation removes development by-products which can influence the course and rate of development.

Another complicating factor is that the oxidized form of the developing agent can in some cases accelerate rather than retard development, as in the case of Lith development.

In addition to the three main types of organic developing agents mentioned above, there are many other types, including heterocyclic compounds and also inorganic ones. Phenidone, or 1-phenyl-3-pyrazolidin-3-one, and related compounds are an important class of heterocyclic developing agents (Figure 8).

Physical development

Physical development involves the reduction of silver ions from solution onto latent image or other nuclei. Solution physical development occurs when silver halide is chemically developed in the presence of a silver halide solvent or silver ion complexing agent. Some silver halide dissolves as a mobile complex and is deposited as silver on the latent image or on silver that has been or is being developed by chemical development. This can be observed as a thickening of the silver filaments often produced in chemical development. Some physical development probably occurs in most developers, even though it may be to a small degree and unintended, because of the presence of some silver ion complexing ability by components present for other purposes, e.g., sulfite ion, and even by *p*-phenylenediamine developing agents themselves.

Direct physical development occurs by design, for example to form an image by transfer of dissolved silver ion from a donor sheet to a nucleated receiver sheet, as in diffusion transfer processing. Model systems to study the chemistry of development conveniently consist of "physical developers" containing developing agent and soluble complexed silver ion from which silver is deposited onto colloidal nuclei suspended in the developer or coated in gelatin on a separate substrate (Figure 9). Silver reduction onto colloidal metal nuclei such as gold, silver, or metal sulfides

Figure 9. Physical development of silver on a spherical catalytic nucleus. DEV, developer.

involves the same electron transfer and proton transfer reactions as in chemical development. The nuclei act in a similar way to the latent image, facilitating electron transfer between the developing agent and silver ion. The nuclei grow as silver is deposited, again in a similar way to the growth of the latent image in the early stages of chemical development.

Various scenarios for the deposition of silver onto colloidal nuclei can be considered. The process could be diffusion-controlled as suggested by Matejec and by Turkevich et al. [36]. In this case the rate was found to be proportional to the radius of the growing spherical nucleus so that:

$$dm/dt = k_d m^{1/3} \quad (25)$$

where m = mass of silver and k_d is a rate constant. On integration the diffusion-controlled growth of a spherical nucleus would be given by Eq. (28),

$$m_t^{2/3} - m_0^{2/3} = k_d t \quad (26)$$

where m_t = mass of silver at time t and m_0 = mass of silver at $t = 0$. In general, however, the deposition of silver from a hydroquinone physical developer onto colloidal suspensions of catalytic nuclei appears to follow a rate law in which the rate of growth is proportional to the surface area of the growing nucleus [37], as described in Eqs. (27) and (28),

$$dm/dt = k_s m^{2/3} \quad (27)$$

$$m_t^{1/3} - m_0^{1/3} = k_s t \quad (28)$$

where k_s is the specific rate constant, see Figure 10 as an example.

Activation energies for the deposition of silver onto gold nuclei are about 12.1 kcal mol⁻¹. The overall rate equation for silver deposition onto gold nuclei is shown

Figure 10. Density^{1/3} vs development time for silver physical development onto gold nuclei (5.52×10^{-6} M), at different concentrations of hydroquinone ($M \times 10^3$) 1 = 0.42, 2 = 0.84, 3 = 1.26, 4 = 1.68, 5 = 2.10. [41a]

in Eq. (29),

$$\text{Rate} = \frac{kK_1[\text{H}_2\text{Q}_\text{T}][\text{Ag}^+]^{0.5}}{[\text{H}^+] + K_1} \quad (29)$$

where k is the rate constant, K_1 is the equilibrium constant for the first dissociation of hydroquinone, and $[\text{H}_2\text{Q}_\text{T}]$ is the total concentration of hydroquinone [38].

The nucleus or development center in physical development can be described as a dual electrode on which the reduction of silver ion to silver and the oxidation of developing agent take place simultaneously. Electrochemical measurements of silver physical development in a hydroquinone/Phenidone physical developer with silver ion complexed with thiocyanate proceed as a catalytic electrode process [39].

The rate of the cathodic reduction of silver ion from silver complexes is rapid compared with the anodic oxidation rate of the developing agent, Phenidone. Thus the physical development rate is governed by the anodic reaction [40]. Charge barrier effects have been seen in physical development as well as in chemical development [41].

Diffusion transfer development

Diffusion transfer development is a photographic processing system which involves both chemical development and solution physical development. Diffusion transfer

refers to the transfer of image chemistry either as dissolved and complexed silver ion or as a dye image. A black-and-white diffusion transfer system has been used in the document copying process called Instafax. In this system two sheets consisting of a donor and receiver are laminated together after passing through a developer containing a silver halide solvent, sodium thiosulfate. The sequence of events is as follows: development of the exposed image in the donor sheet, dissolution of the undeveloped silver halide in the donor sheet, diffusion of the dissolved silver ion to the receiver sheet, physical development onto nuclei in the receiver sheet followed by peel-apart of the two sheets to reveal a positive image in the receiver sheet and a negative image in the donor sheet. The nuclei coated in the receiver sheet can be silver, gold, or metal sulfides such as silver sulfide, nickel sulfide, cadmium sulfide, and zinc sulfide.

In another version of the system described above the physical development nuclei can be coated in the same sheet below the silver halide layer, which is designed to “wash off” during processing, leaving the positive image behind.

Color systems based on diffusion transfer can be made by means of dye developers (Polaroid) which are coated with a negative silver halide emulsion. Upon development the dye developer becomes immobilized, whereas in the unexposed non-developing areas the dye diffuses to a mordanted receiving layer either in a separate peel-apart sheet or in the same sheet.

Reversal processing

In reversal processing a direct positive image is obtained by using either a reversal emulsion or a normal negative emulsion in which the process has two development steps. In color reversal processing used for transparency production, the first step is a black-and-white development using a hydroquinone–Phenidone mixture which brings up a negative silver image. The unexposed silver halide is then either light-exposed or chemically fogged using strong reducing agents such as borohydride, aminoboranes, or stannous chloride. Unlike the development reaction, the chemical fogging action of borohydride is indiscriminate and electron injection will occur for all silver halide grains, forming developable centers. If the film contains incorporated color-forming couplers and the second development step uses a color developer, then a direct positive color image is formed. The silver image is then oxidized and removed to reveal the color image.

Superadditivity

Superadditivity is a synergistic phenomenon in which a primary developing agent and a secondary developing agent are used together to provide a more active developer than either can provide singly. Levenson [42] has identified “superadditivity of densities” and “superadditivity of rates”. Superadditivity of densities arises as indicated in Figure 11, in which the broken curve for the arithmetic sum ($A + B$) is computed by adding the rates for A and B . Superadditivity is shown only if the curve for “ A with B ” lies above the broken curve. By considering only the densities reached in time T , curves lying between A and $A + B$ would give an erroneous impression of superadditivity [38].

Figure 11. Diagrammatic time vs. density curves for two developers with agents A and B and for the combined developer ("A with B"). Slope rates at a finite density D are shown inset.

Thus "density superadditivity" is only an apparent superadditivity even though the sum of the silver densities for the separate developers A and B appears to be less than that for the A + B curve. This is because developer B would not have an induction period in the presence of developer A and so would contribute to the overall development almost immediately, giving the broken curve A + B which is merely additive. In kinetic terms, true superadditivity occurs when the rate of growth of density or silver for the combined "A with B" developer is greater than the sum of the rates of growth of density or silver for the A developer and the B developer separately.

This is shown clearly in the data of Lee and James [43] in Figure 12, in which the sum of the separate rates of development increases to a maximum for a given ratio of the two developing agents, hydroquinone and Phenidone.

Hydroquinone and *N*-methyl-*p*-aminophenol (Metol) form superadditive mixtures and a complex, "Metoquinone", consisting of one hydroquinone and two Metol molecules, was proposed by Lumière, Lumière and Seyewitz [44] to be the species with higher activity than the separate agents. A similar complex between hydroquinone and 1-phenyl-3-pyrazolidinone (Phenidone) consisting of one molecule of hydroquinone and one molecule of Phenidone has been observed in the solid state by Kurosaki [45] and Mutter and Schneider [46]. Although these complexes can be crystallized from concentrated solutions of hydroquinone and Metol, and hydroquinone and Phenidone, there is no evidence of their existence in solution.

Figure 12. Relation between the rate of chemical development and the ratio of developing agents present (0.01 M = 100 %); solid lines, theoretical curves obtained if the rates were additive; dashed lines, experimental curve [43].

Hydroquinone and *N*-methyl-*p*-aminophenol (Metol) form a superadditive mixture which was shown by Tausch and Levenson [47] to involve the consumption primarily of hydroquinone with the preservation of Metol. This led to the regeneration theory proposed by Levenson, that Metol was acting as the developing agent at the silver halide surface and that oxidized Metol was reduced back to Metol by hydroquinone as outlined in Eqs. (30)–(33).

In order for hydroquinone to be effective in regenerating Metol by the mechanism proposed, it is necessary that the quinone reacts with sulfite more rapidly than does methylquinoneimine.

Thus superadditivity can be viewed as a sequence of two types of electron transfer reaction, one which is heterogeneous between Metol and the latent image, resulting in silver development, and one which is homogeneous between hydroquinone and

oxidized Metol, resulting in the regeneration of Metol. It is also possible that the second electron transfer is also heterogeneous in which the adsorbed oxidation product of Metol is regenerated on the surface.

Effective superadditive mixtures result from combinations of 1-phenyl-3-pyrazolidinone (Phenidone) [48] and its derivatives with hydroquinone, ascorbic acid, *p*-hydroxyphenylaminoacetic acid, hydroxylamines, pyrogallol, and other agents. In general, superadditivity is a phenomenon primarily used in black-and-white developers but it has also been observed in color development [49].

A similar regeneration scheme to that proposed by Levenson also applies to Phenidone/hydroquinone developers. Phenidone (P) undergoes a heterogeneous one-electron transfer with exposed silver halide to form a relatively stable radical R^{\bullet} (Eq. (34)), which can then undergo an irreversible dismutation ($k = 170$ to $570 \text{ M}^{-1} \text{ s}^{-1}$) [50], to give P and the fully oxidized 1-phenylpyrazolidinone Py (Eq. (35)). The radical R^{\bullet} can undergo a homogeneous one-electron transfer with hydroquinone to give P and oxidized hydroquinone. Ionized Phenidone (P^-) exists at pH 10.0, which is a common developer pH. HQ^- is the half-ionized form of hydroquinone which also exists at pH 10. $S^{\bullet-}$ is the semiquinone of hydroquinone, and Q is benzoquinone.

The semiquinone, which is a relatively stable species, can undergo an irreversible dismutation (Eq. (37)) or react with another R^{\bullet} (Eq. (38)), although the latter reaction is unlikely at low levels of $S^{\bullet-}$.

Regeneration of one developing agent by another is not in itself necessarily an explanation of a superadditive rate of development, even though it clearly occurs. In its simplest form regeneration would merely maintain the concentration of the primary developing agent and prevent loss of development rate by exhaustion. It appears necessary to suppose that regeneration has some additional effect, such as:

- 1) the removal of an inhibiting oxidation product; or
- 2) generation of a more active species, such as a semiquinone; or
- 3) a lowering of the limiting effect of diffusion control by regenerating the active(primary) developer with the inactive(secondary) developer, thereby increasing the apparent concentration of the primary developer; or
- 4) combination of regeneration with action according to the charge-barrier theory of development. The charge-barrier theory of James [51] was proposed to explain the kinetic behavior of differently charged developing agents (see the section on

- “Change in silver halide caused by development”) and could also be used as a mechanism of superadditivity. In this case the induction period of negatively charged agents such as hydroquinone, which occur according to the charge-barrier theory because of a negative charge barrier at the silver halide surface, is removed by an uncharged or positively charged auxiliary developing agent, or
- 5) acting as an “activator” for the secondary developer which is relatively inactive by itself, as in the electrochemical theory of catalytic currents outlined below.

Superadditivity has been observed in both chemical and physical development [52]; thus the presence of silver halide is not a necessary condition for its occurrence but is likely to modify its detailed course. This would appear to rule out the charge-barrier theory in its original form, although charge effects might also occur at silver as well as at silver halide surfaces.

The removal of an inhibiting oxidation product was demonstrated by Levenson and Twist [52c] in studies of physical development onto colloidal nuclei. In this case the very early stages of silver ion reduction were followed and it was found that silver ion reduction by Phenidone was initially high but fell after less than 1 min to a much lower rate (of about $1/25$ of the initial rate; see Figure 13) even though only 30 % of the Phenidone had been consumed. It is suspected that this inhibition is due to the Phenidone radical. The addition of hydroquinone, which did not develop by itself under these conditions, restored the initial rate of development by Phenidone.

Figure 13. Physical development with Phenidone, showing the high initial rate followed by a slower rate ($1/25 \times$ the initial rate). Hydroquinone addition (1.38×10^{-4} M) after the slow rate is established restores the initial rate [52c].

This indicates that superadditivity arises by the removal of an inhibiting species in Phenidone oxidation, probably the Phenidone radical as in case 1 above. Lee and Miller [53] showed that development of silver halide by the Phenidone radical generated in a flow system was much slower than that by Phenidone itself by a factor of about 24, which agreed very closely with the results of Levenson and Twist [52c], and Shiao and Dedio [54] also found that superadditivity of ascorbic acid and a Phenidone derivative (MHP) was explained by scavenging the MHP radical, thus eliminating any inhibition. A similar inhibition by oxidation products of development was proposed to explain the behavior of ascorbic acid physical developers [55].

Electrochemical measurements by Jaenicke and co-workers [56] indicate two possible mechanisms by which superadditivity could arise. In the first, a developer showing irreversible oxidation becomes reversible in the presence of a second developing agent. In the second, when the mixed potential is in the limiting current region of the anodic reaction, superadditivity occurs if the limiting current rises because the number of electrons delivered per molecule of a first developer, for example hydroquinone, is increased by the addition of a second developer, such as Phenidone. This could happen with hydroquinone development in the presence of sulfite because the reaction product, hydroquinone monosulfonate, is a poor developer by itself but in the presence of Phenidone it is activated.

Regeneration of the second developing agent could be envisaged to take place either homogeneously or heterogeneously. The theory of catalytic currents in electrochemical kinetics is equivalent to homogeneous regeneration and some studies by Jaenicke and Kobayashi [57] indicate that the catalytic processes could be:

where Z and B are essentially electroinactive under the conditions used and the catalyst is the system Red/Ox. In the hydroquinone/Phenidone system Red is Phenidone and Ox is the Phenidone radical, Z is oxidized hydroquinone and B is hydroquinone. The limiting catalytic current at a rotating disk electrode for a process as indicated by Eqs. (39) and (40) has been derived [58] according to Eq. (41), where

$$i_c = nFC_{\text{red}}(Dk_f C_z)^{1/2} \quad (41)$$

D = the diffusion coefficient of Red, and C_{red} and C_z = bulk concentrations of Red and Z.

Anodic catalytic waves for hydroquinone were observed at a rotating gold electrode, confirming the regeneration mechanism with a rate constant for Phenidone regeneration of $1.3 \times 10^6 \text{ L mol}^{-1} \text{ s}^{-1}$ [57].

Physical development can occur on nuclei with the simultaneous reduction of silver ion and oxidation of the developing agent. The two partial processes can also be separated in a model cell so that the effect of solution composition on the separate anodic and cathodic parts can be seen (Figure 14). Kawashima et al. [59]

showed that the development rate of a thiocyanate developer with Phenidone/hydroquinone and Phenidone/ascorbic acid agreed with that calculated from the theoretical equation for the catalytic current, and indicated no effect of thiocyanate on the anodic process. Superadditive mixtures based on the silver thiosulfate complex showed inhibition of the anodic process by adsorbed thiosulfate.

Lith development

In Lith development, very high-contrast silver images are produced and used to form half-tone dot images in the process called lithography. Lith development occurs with high-chloride silver halide monodisperse emulsions [60] and is characterized by a long induction period which is exposure-dependent, followed by sudden rapid development in regions of higher exposure.

A comparison of conventional, Lith and nucleated development is shown in Figure 15.

Lith developers are based on hydroquinone and have a low level of sulfite ion which is critical for the high contrast to be obtained. In conventional developers based on hydroquinone, a relatively large amount of sulfite ion is present which removes the oxidation products by sulfonation. In Lith developers the low sulfite ion concentration allows the buildup of oxidation products which can accelerate

Figure 15. A diagrammatic comparison of non-Lith development, conventional Lith development, and nucleated development.

development. One mechanism proposed by Yule [61] suggests that the oxidation products of development, benzoquinone and hydroquinone semiquinone, are responsible for the rapid phase of Lith development. Eggers [62] has shown that in the absence of hydroquinone, *p*-benzoquinone itself acts as a Lith developer, but only after prolonged times of about 16 min. He also showed by ESR measurements that hydroquinone semiquinone is formed at pH 10 in solutions of *p*-benzoquinone by the action of OH^- ions. This suggests that *p*-benzoquinone is not directly responsible for the Lith effect but that the hydroquinone semiquinone is. In addition to any hydroquinone semiquinone generated by the action of OH^- on *p*-benzoquinone, hydroquinone semiquinone is generated in a rapid equilibrium between hydroquinone and unsulfonated *p*-benzoquinone. This view is supported by more recent investigations of Hefter [63] in which the buildup of semiquinone was demonstrated by ESR spectroscopy in hydroquinone development. Work by Umberger and Herbert [64] supports the view of Lith development being based on development acceleration by the accumulation of hydroquinone semiquinone. The slow stage of Lith development can be outlined as in Eqs. (42)–(44).

Lith developers operate at about pH = 10.0 and as a consequence the main developing species is the mono-anion (HQ^-) of hydroquinone ($\text{p}K_a = 9.91$), which

is a relatively weak developing species, unlike the di-anion of hydroquinone ($pK_a = 11.56$), which is much stronger. During the induction period or slow stage in Lith development the low level of sulfite is sufficient to remove *p*-benzoquinone to give the sulfonated product, which is a weaker developer than hydroquinone, and development proceeds at a relatively slow pace. As the latent image size increases and the sulfite is used up, a second phase of development can start.

The semiquinone $S^{\cdot-}$ can also undergo the reversible dismutation reaction mentioned above, but in Eq. (45) we write it the opposite way round for clarity. This reaction is very rapid ($k = 10^8 \text{ M}^{-1} \text{ s}^{-1}$) [67] and controls the semiquinone concentration.

It is proposed that the semiquinone is an active developing agent, estimated by Umberger [64] to be 10 times as active as the hydroquinone dianion. The low sulfite level in Lith developers allows the *p*-benzoquinone (Q) to build up, which boosts the semiquinone concentration via the dismutation reaction. The increased semiquinone level accelerates development which produces more *p*-benzoquinone and semiquinone according to Eqs. (46), (47),

and so on, giving an exponential form of development.

The acceleration of development occurs in exposed grains adjacent to already-developing grains and although Lith development is sometimes referred to as “infectious development” there appears not to be any gross migratory development acceleration. This implies that the accelerating species are not fogging agents as in some materials described in the section on “Nucleated development”. James [65] has shown, however, that a motion picture positive film that has been partially developed in a hydroquinone developer containing quinone retains its increased rate of development even after thorough washing followed by development in a quinone-free hydroquinone developer. This clearly indicates an additional factor in which the film has been permanently altered by hydroquinone oxidation products, which is not apparent in the Yule mechanism. This can be resolved if it is possible that hydroquinone oxidation products can chemically latensify latent sub-images, rendering grains developable which would otherwise not be developable.

Hydroxyhydroquinone has also been suggested as one of the reaction products of *p*-benzoquinone with hydroxyl ions which might cause the Lith effect [66]. Another mechanism suggested by James [67] involves the reaction of the oxidation products of hydroquinone with the amino groups of gelatin to form amino-substituted species which might act in a superadditive manner with hydroquinone to accelerate development and cause the Lith effect. Another alternative mechanism proposed by Zwicky [68] involves a “silver ion hypothesis” in which silver ion is solubilized by liberated halide ions in the vicinity of rapidly developing grains. The mobile silver

ions are then physically developed on filaments and on developing centers in adjacent grains to give the Lith effect. This latter mechanism appears to conflict with the known effect of sulfite ion on Lith development, which is to suppress it entirely. Sulfite ion is a strong solubilizing agent for silver chloride but not silver bromide. Increasing levels of sulfite ion should therefore enhance the concentration of mobile silver ion, enhance any physical development effects, and on the basis of the silver ion hypothesis enhance the Lith effect.

Although the mechanisms described above are reasonable it should be emphasized that the main effect of oxidation products of development is a retarding one, as indicated in the section on "Changes in silver halide caused by development", above. This basic property is still present even though other reactions of the development oxidation products can have dramatic effects. In this regard it has also been suggested [67] that some of the restraint in weakly exposed areas in Lith development is due to the retarding action of quinone.

Suga [69] has further outlined the "redox-Lith effect" in which quinone can oxidize latent image centers. Smaller latent image centers are oxidized, thus retarding image formation at lower exposures, whereas larger latent image centers are unaffected, allowing development to occur. The overall effect is to promote high-contrast development as observed in the Lith process.

Another possibility that could explain Lith development is the apparently contradictory phenomenon of "bleach enhanced fog" or BEF [70]. In this case compounds known as silver bleaches can cause fog in grains with sub-developable silver centers. Two-atom silver centers cannot initiate development and would be bleached by oxidants, for example, benzoquinone, to a one-atom silver center. A single silver atom is thermally unstable and can dissociate, without the need for an oxidant, into a silver ion and a mobile conduction-band electron. If several two-atom centers are present on a grain, a developable center can arise from the accumulation of these mobile electrons at a suitable site.

Infectious or nucleated development

High-contrast halftone dot images can now be produced by development of a special film, such as Kodak Ultratec Film [71], which contains incorporated nucleator precursors. The end result is similar to that of Lith development but the images are of higher contrast and higher photographic speed, less sensitive to processing conditions, and can be developed in a superadditive developer and so be formed more rapidly. The usual nucleator precursor is a phenyl formyl hydrazide which reacts with oxidized developing agent to generate a strong nucleating species. The nucleating species is capable of direct electron injection into sub-developable and unexposed silver halide grains close to an exposed developing grain to generate a developable grain. The mechanism can be described by Eqs. (48)–(53).

Thus exposed grains develop, and oxidized developing agent reacts with the nucleator precursor to generate the nucleator ($\text{R}_1\text{-Phenyl-N=NH, N}$) which is capable of direct electron injection into silver halide to create developable grains adjacent to an already developing grain. These nucleated grains develop, producing more nucleator, and so the effect is a cascade; all grains above a toe exposure will develop giving a high-contrast image. Recent work [72] has confirmed the mechanism outlined above and that the nucleator species (N) is capable of direct electron injection into silver halide.

Proximity development

This type of development has been reported by several workers and occurs at high coverages of silver halide, i.e., about 2 g m^{-1} [73]. As the amount of silver halide coated is increased, more silver is developed than expected and in addition anomalous granularity measurements are obtained. If a silver halide emulsion is coated and developed, a normal development is observed. If the same silver halide emulsion is pre-exposed before coating, then coated and developed, most of the silver develops regardless of further exposure after coating. If now a proportion of pre-exposed silver halide is coated with unexposed silver halide, then it is found that more silver is developed than the sum of the exposed and unexposed coated separately. This effect is only significant as the total amount of silver halide coated is increased to high levels, and the effect increases with coating level. This indicates some interaction between exposed and unexposed grains and is likely to be due to physical contact of developed and developing silver with adjacent unexposed grains. Electron transfer from the silver of a developing grain then initiates development in an unexposed grain, which once started will proceed.

Redox amplification

Another oxidant in addition to silver halide has been employed for a variety of photographic systems, one of which is the dye bleach system of Schinzel [74] (see Section 1.3.6) in which direct positive images are formed by bleaching dyes catalyzed by a silver image. A system for the catalytic reduction of dyes to produce color images was described by Gaspar [75]. Matejec [76] formed dye images from palladium, gold, and silver nuclei and from photographically produced silver by the catalytic oxidation of *N,N*-diethyl-*p*-phenylenediamine with sodium perborate and hydrogen peroxide. This method of dye formation has been called RX or RedoX amplification. Bissonette [77] has used other oxidants such as cobalt(III) complexes, e.g., $\text{Co}(\text{NH}_3)_6\text{Cl}_3$ (COHEx). Peroxy compounds such as perborate and hydrogen

peroxide have been commonly used, particularly with photographic layers where the main light-sensitive material is silver chloride, whereas COHEX materials work better than peroxide with silver bromide light-sensitive materials.

An RX developer based on hydrogen peroxide is shown in Table 4.

In RedoX or RX development the mechanism involves an additional stage or reaction in the process leading to dye formation. If the color developer solution contains a special type of oxidant, a silver metal catalyzed oxidation of color developing agent occurs which then results in dye formation independent of normal silver development and dye formation. This reaction is imagewise since it is catalyzed by the silver image formed by conventional development and as a result there is a further amplification factor (about 10×) in addition to that of normal silver halide development. The overall reactions involved where hydrogen peroxide is the oxidant are given in Eqs. (54)–(56).

The third reaction of the sequence is the silver-catalyzed oxidation of color developing agent which leads to dye formation by coupling as in normal color development. This process allows a lowering of the coated silver level but still produces a full-density color image (Figure 16). Typically the coated silver level is 10 % of that required for normal color development, which means that 90 % of the dye image is formed by the RX amplification reaction.

Figure 16. Dye density versus relative log exposure for a low-silver coating (a) developed normally and (b) developed in an RX amplifying developer.

In the same way that the latent image and image silver catalyzes the electron transfer reaction between color developing agent and silver halide, the silver image catalyzes the electron transfer reaction between the developing agent and hydrogen peroxide. In this case the hydrogen peroxide takes the place of silver halide as the oxidant. The drawback of this is that the lower silver halide level results in a smaller number of silver halide grains per unit area and thus a higher granularity.

One particular practical difficulty with RX photographic developers is their instability. The combination of a developing agent and an oxidant in the same solution leads inevitably to decomposition of the developing agent and the solution becomes unusable. The stability of RX developers like that in Table 3 have been examined by Wildman et al. [78], who identified several factors that show an improvement which allows RX developers to be used in a normal processing machine.

Nickel and Liu [79] have studied the silver-catalyzed oxidation of *N,N*-dimethyl-*p*-phenylenediamine by $\text{Co}(\text{NH}_3)_5\text{Cl}_3$ by means of a silver colloid and a rotating silver electrode. They conclude that the reaction can be quantitatively explained by means of the theory of mixture potential and mixture current of Wagner and Traud

[80]. The electrocatalytic reaction starts with electron transfer from *p*-phenylenediamine to the cobalt(III) complex via the silver at a high reaction rate. A competitive reaction involving the oxidative formation of silver halide then begins. This silver halide may be reduced by *p*-phenylenediamine, which is thus oxidized directly by the cobalt(III) complex and also by the silver halide formed by the oxidation of silver.

Latent image bleaching

This is a phenomenon which has been referred to in Lith development but it has also been observed in conventional color development. A strongly developing grain produces development by-products which are capable of influencing the course of development of other grains nearby. If the developing grain has a neighbor which is slow to start developing, then the oxidized developer formed by the strongly developing grain can theoretically diffuse in the layer and bleach the latent image on the neighbor [81]. The release of halide ions during development of the strongly developing grain will enhance this effect by lowering the silver ion potential. The effect is shown in Figure 17.

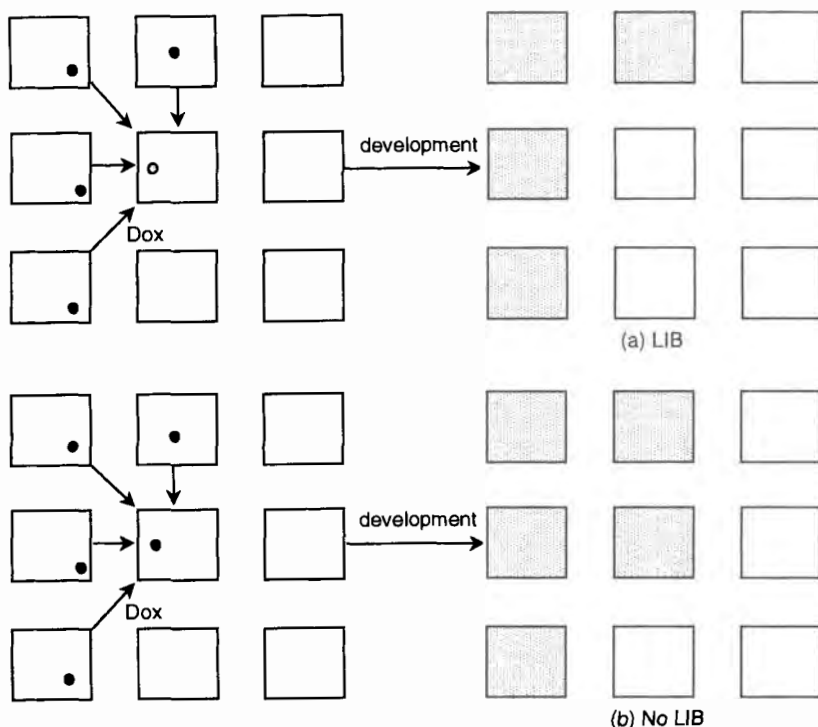

Figure 17. (a) Latent image bleaching by development products generated by adjacent developing grains; (b) development without latent image bleaching (LIB).

A method of demonstrating that this effect can occur in color development was described by Jarvis and Twist [81e]. This involves a two-stage development procedure:

<u>Process P1</u>	<u>Process P2</u>
Develop C-41	Develop C-41 + sodium ascorbate
Wash	Wash
Develop C-41 + sodium ascorbate	Develop C-41
Fix	Fix
Wash	Wash

Kodak C-41 developer is the standard developer for color negative films and it is in this developer that the occurrence of latent image bleaching (LIB) is being tested. Sodium ascorbate is a strong developing species which does not have a sufficiently stable oxidation product to cause LIB; it also removes the oxidation products of the color development that are formed in C-41 developer. The two types of development, P1 and P2, give the same total development but with the two development steps reversed. If LIB does not occur, then P1 and P2 will give the same result. If LIB occurs, then at some exposures P1 will show less development and a smaller number of developed grains, because in P1 the stage at which LIB could occur, with C-41 developer, comes first. In P2 C-41 developer comes second, after most of the development has already occurred, and so LIB is not possible.

The result is shown in Figure 18, a LIB diagram [82], which shows that latent image bleaching has occurred in P1 and that the lower density in the image is associated with a smaller number of developed grains. Most of the LIB occurs in the mid to upper scale and not in the regions of lower exposure. Another phenomenon was observed which has been called developer-induced fog (DIF), which occurs in the toe and unexposed regions. The latter was attributed to electron injection into unexposed grains by the color developer semiquinone, rendering them developable.

Redox buffers and the critical size of latent image centers

In practical developers there is usually an excess of the reduced form of the developing agent with a small and variable amount of the oxidized form. Except for certain cases, such as in Lith development, the oxidation products are not allowed to accumulate. This means that the redox potentials are uncertain because the system is not in equilibrium. Redox buffers are solutions which are in equilibrium and contain definite amounts of oxidized and reduced forms. Many organic developing agents have oxidized forms which undergo side reactions, particularly in alkaline solution, which prevent them from being used as redox buffers; for that reason, metal ion couples are used instead.

The reversible redox reaction of iron(II)/iron(III), usually complexed with a suitable ligand, is ideal for this purpose. The redox reaction

where C is a complexing agent, has redox potentials which depend on the ratio of

Figure 18. Two-stage development method to reveal latent image bleaching during development [86].

$\text{Fe}^{2+}/\text{Fe}^{3+}$, so if air is excluded from the system a range of redox buffers can be made with definite potentials by adjusting this ratio. The complexing agent C can be oxalate [83], citrate, tartrate, ethylenediamine tetraacetate (EDTA), DTPA, or other amino carboxylic acids.

Early in Section 1.2.2 it was shown that if the potential of a developing agent is more negative than the silver ion potential, then development or silver ion reduction is thermodynamically possible. The difference between the equilibrium silver potential E_{Ag} and the developer or redox buffer potential E_{dev} is:

$$\Delta E = E_{\text{Ag}} - E_{\text{dev}} \quad (58)$$

Thus redox buffers with potentials more negative than the silver ion potential (ΔE positive) would be expected to grow latent images and those with potentials more positive (ΔE negative) than the silver ion potential would be expected to bleach latent images. Several workers [84] have shown that development starts only when the potential is some 50–160 mV more negative than the equilibrium potential of bulk silver. It was also shown by Hillson [84b] that redox buffers with a potential more positive than the silver potential eventually destroyed all the surface latent image, as expected, whereas redox buffers with a potential more negative than the

Table 5. Typical redox buffer solution [86].

Ion	Concentration (M)	Substance
Fe ²⁺	0.2	(NH ₄) ₂ Fe(SO ₄) ₂ · 6H ₂ O
Fe ³⁺	0.01–0.2	Fe(NO ₃) ₃ · 9H ₂ O
Citric acid	0.15	(CH ₂ COOH) ₂ C(OH)CO ₂ H
Ag ⁺	0.001	AgNO ₃

silver potential proceeded to a limiting value which was ascribed to the destruction of all latent image centers smaller than a critical size. Larger centers were not destroyed but were enlarged by the redox buffer. Thus, by using a series of buffers with different redox potentials, it is possible to grade surface latent images into size classes and to determine the redox potentials of these size classes. The cause of the shift in redox potential has been ascribed to the higher free energy of small silver particles compared with that of bulk silver, although Matejec and Moisar [85] believe that latent images have a similar potential to bulk silver. Some of the differences between interpretations might be due to the presence of gelatin and its effect on the stability of small silver particles and on the redox potential that actually pertains in the layer [84c]. In order to resolve this Galashin and Senchenkov, and later Konstantinov et al. [86], looked at the effect of redox buffers on the stability of evaporated silver particles. The composition of a typical redox buffer solution is shown in Table 5. The redox potential is changed by varying the ferric nitrate concentration and then measured using a platinum electrode and calomel electrode.

The Gibbs–Thomson equation describes the effect of the size of a small particle on the potential relative to that of the bulk material. For silver particles:

$$\eta_r = E_{\text{Ag}} - E_r = \frac{2\sigma V_m}{rF} \quad (59)$$

where E_{Ag} is the equilibrium potential for the bulk silver electrode, E_r is the potential of a microscopic silver electrode of radius r , V_m is the molar volume of silver metal, and σ is the specific free surface energy of the metal/solution interface. From Eq. (58),

$$\Delta E_r = \Delta E - \frac{2\sigma \cdot V_m}{rF} \quad (60)$$

which is the potential acting on small silver particles. In a given redox buffer there will be a critical size r_0 for which

$$\Delta E_{r_0} = \Delta E - \frac{2\sigma \cdot V_m}{r_0 F} = 0 \quad (61)$$

so that the potential difference η_{r_0} at which a silver particle is just in equilibrium in a redox buffer is given by

Figure 19. Histograms of samples treated in a chemical developer having $\Delta E = 19.3$ mV. The arrows indicate the stable critical size class r_0 . (A) uncoated with gelatin, development 120 min; (B) overcoated with gelatin, development 180 min. In the presence of gelatin the size of the stable specks is considerably smaller [86].

$$\eta_{r_0} = \Delta E = \frac{2\sigma \cdot V_m}{r_0 F} \quad (62)$$

Konstantinov [86] observed a minimum in the size distribution curve at the size class corresponding to r_0 after short treatment times in a redox buffer (Figure 19). The minimum occurs because particles at the extremes of size class r_0 dissolve or grow, and thus the size class is depleted from two directions; it disappears after prolonged treatment and the distribution moves to larger sizes. The critical size r_0 is inversely related to ΔE of the redox buffer as required by the Gibbs–Thomson equation. This is illustrated in Table 6.

Further work [86] showed that the specific surface free energy of silver particles was the same whether they were evaporated on carbon or silver bromide, but was lowered by coating with gelatin. The latter is given as the reason for the stabilizing effect of gelatin on latent image specks.

Cramp and Hillson [87] have shown that the Gibbs–Thomson equation, which from a thermodynamic viewpoint should be valid only for large assemblies of atoms, appears to be valid down to latent images with only 12 atoms (Figure 20).

Table 6. Critical particle size versus redox potential.

r_0 [Å]	ΔE [mV]
30 ± 3	66.8
39 ± 3	50.7
43 ± 3	43.8
70 ± 4.5	26.5
192 ± 17	10.0

Figure 20. Pre-filamentary growth of development centers: t is development time and n is the number of silver atoms in the developing center. Note the sharp change in activity when n is about 12 atoms [87].

They have estimated that due to the excess energy of very small particles the induction period for development increases sharply for clusters of less than 12 atoms. This effect has been cited to explain discrimination in chemical development of silver halide, on which practical photographic systems depend. The excess energy of small particles slows down the early stages of development to provide this discrimination between exposed and unexposed grains.

The effect of gold sensitization of emulsions is to alter the shape of the curve shown in Figure 20 because of the incorporation of gold into the latent image. Gold is more active than silver as a catalyst for silver deposition [88] and also has been shown to be able to catalyze development with a two-atom center, compared with the minimum of four atoms for silver. The curve will now come down more steeply and not turn over to long induction periods until n is very small.

Hada et al. [89] compared experimental characteristic curves with theoretical curves based on a model of exposure and development. A marked difference in the ability of specks to initiate development was found between silver specks smaller than Ag_4 and those larger than Ag_4 .

Tani [90] has examined the properties of silver clusters by means of redox buffer solutions, and showed that the oxidation potential of latent images formed by sulfur-plus-gold sensitization was much more positive than for those formed in unsensitized, sulfur-sensitized, reduction-sensitized, and iridium-sensitized emulsions. The oxidation potential of fog centers with excessive sulfur sensitization was much more positive than that of fog centers with excessive reduction sensitization. In general this reflects the relative ease of bleaching of silver centers compared with silver sulfide centers.

Kawasaki et al. [91] looked at the oxidation kinetics of large photolytic silver clusters in redox buffer solutions. The process was analyzed in terms of a series of stepwise reactions involving electron transfer and silver ion elimination. It was shown that the single-step oxidation:

proceeds via the steps:

and not via:

The ionization potential of Ag_n and the dissociation energy of Ag_n^+ are the dominant factors influencing oxidation. It was concluded that with increase in cluster size the ionization potential decreases and the dissociation energy increases.

Mostafavi et al. [92] generate very small silver aggregates by a pulse radiolysis method and follow their aggregation and growth in the presence of an electron donor, the radical anion of sulfonatopropyl viologen (SPV) generated in the same pulse. They use this method to study the size dependence of the electrochemical potential of small silver clusters and conclude that a critical silver aggregate is $\text{Ag}_5^+/\text{Ag}_5$, which has $E^\circ = -410 \text{ mV (NHE)}$.

Ohzeki [93] has examined the rate of development and size of latent image centers in chemically sensitized emulsions. He concludes that there are fast and slow components in development and that the fast component corresponds to latent images of five atoms or more and the slow component to latent images of less than five atoms. The fast component can be explained by electrode reaction theory whereas the slow component can be explained by the stepwise one-by-one growth of the latent image center, which results in a long induction period for development of grains with less than five atoms.

Federov and Zakarov [94] studied the thermodynamics of silver particle growth. Silver particles have a critical size which can initiate development, whereas particles of smaller size can grow only by coalescence.

Tani [95] has reviewed the properties and formation of silver clusters on silver halide grains. It is demonstrated that latent image centers composed of four atoms are formed with high efficiency and bring about large-scale amplification during development.

Development mechanism

In the classical theory of Ostwald, Abegg, and Schaum [96] the homogeneous reduction of silver ion is assumed to be rapid and is followed by the physical deposition of silver on a latent image nucleus from a supersaturated solution of silver. The term “physical development” arises from this description and developers used at this time often deliberately contained soluble silver ion. It is now considered that physical and chemical development are both chemical, or electrochemical, processes in which silver ion reduction occurs at the latent image surface.

The latent image catalyzes the reduction of silver ion either from the solid silver halide phase, as in chemical development, or from a soluble source of silver ion, as in physical development (Figure 21). One view of chemical development is that interstitial silver ions move through the silver halide crystal and are reduced on the underside of the latent image speck. In purely physical development complexed silver ion moves through the solution and is reduced on the nucleus. In this sense physical development and the early stages of chemical development are similar.

The main difference between the two types of development depicted in Figure 21 is that the silver ion source is from a limited direction (anisotropic) underneath the latent image in chemical development but is from every direction (isotropic) in purely physical development. This difference has been used to explain the filamentary nature of the silver formed in the rapid or continuation stage of chemical development. It appears that in the early stages of chemical development the latent image grows but subsequently silver filaments are “extruded” from the silver halide grain. In the Gurney and Mott [97] theory of development silver filaments are “extruded” due to

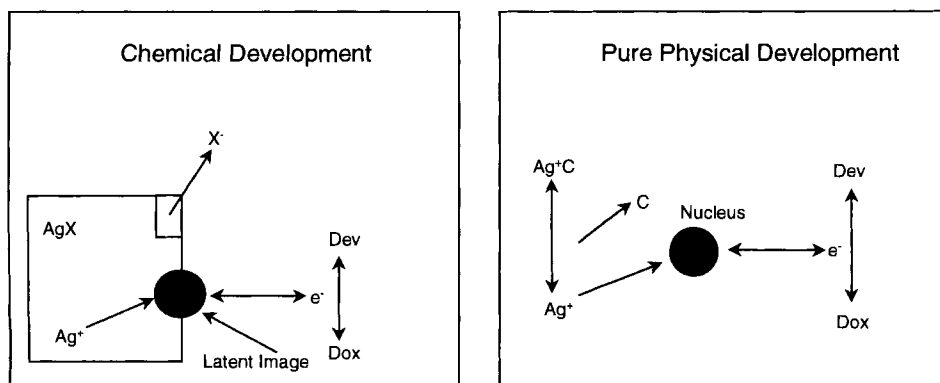

Figure 21. Chemical and physical development. In chemical development the silver ion source is solid silver halide. In physical development the silver ion source is a soluble silver ion complex.

Figure 22. Metallic silver growing at an AgBr surface. The spherical particle becomes elongated when the diameter of the sphere grows too large for the silver to diffuse over the whole sphere in the time available. Typical 200 Å filaments are 70 atoms wide [98].

the pressure of silver atoms accumulating on the underside of the latent image speck.

The spherical growth of the latent image will accelerate because of the increase in surface area and Berry [98] suggested that once the rate reaches a value such that the rate of diffusion of silver atoms on the surface of the growing speck is unable to maintain a spherical shape, silver filaments move out from the grain surface.

It has been shown by Metz and confirmed by Miura and Sakaguchi [99] that the far end of a filament is the part originally on the surface, thus indicating that the primary filament grows out rather than being formed by deposition of silver from outside the silver halide grain (Figure 22).

Filaments can be single strands or loops and it is likely that the base of the filament can split to form a branch and rejoin to form a loop (Figure 23).

It is known, however, that in the development of silver halide in the presence of silver halide solvents, thickening of filaments formed originally by chemical development occurs by solution physical development on the surface of the filament. It has also been suggested that the silver halide grain can dissolve on the underside of the latent image speck, thus providing soluble silver ions which can then be reduced by physical development on the base of a growing filament (Figure 24). In this sense chemical development then becomes a version of solution physical development and the distinction between chemical and physical development is blurred.

Matejec and Meyer [101] suggest that the concentration of interstitial silver ions is insufficient to account for the rates of development observed in practice. Calcu-

Figure 23. The sequence, a to f, schematically shows the generation of the filament loop. A transition of the kind c–d¹, i.e., the tearing-off of a filament from the AgBr surface, is a rare occurrence [99].

Figure 24. Schematic representation of filament growth (A) by silver ion transport through the crystal and extrusion, and (B) by dissolution of the AgBr followed by reduction of silver ions in the vicinity of the growing filament [100].

lations by Milchev and Malinowski [102], however, support the view that there is no limitation caused by insufficient silver ion flux through the silver halide crystal.

Absolute reaction rate theory considers the formation of an activated complex intermediate between reactants and products (Figure 25). The activated complex can decay to products or back to reactants. Heterogeneous catalysis considers the adsorption of reactants as a means of lowering the activation energy of reaction which occurs on the surface followed by desorption of the products. The mechanism of development can be considered as a combination of these ideas.

Figure 25. Schematic representation of the activation energies involved in the homogeneous and heterogeneous reduction of silver ions.

Here the activated complex that is formed between the developing agent and silver ion does not decompose significantly to products in the homogeneous phase. If the activated complex forms in the adsorbed state on the latent image surface, then the activation energy for reaction is lowered and products are formed. Thus the latent image acts as a heterogeneous catalyst. The rate of the reaction will depend on the activation energy by means of the Arrhenius relation (Eq. (68)) where E_a is the activation energy of the reaction. The pre-exponential factor A (Eq. (69)) contains reactant concentrations, a rate constant, k , and the catalyst surface area, S .

$$\text{Rate} = A \exp(E_a/RT) \quad (68)$$

$$A = k[\text{Dev}]^\alpha [\text{Ag}^\oplus]^\beta S \quad (69)$$

The fractional order can be explained by means of the surface coverage of adsorbed components which becomes more difficult as it approaches a complete monolayer. The heat of adsorption decreases with the extent of adsorption because of the increasing closeness and interaction of adsorbed species. This can be interpreted by means of an adsorption isotherm such as the Freundlich isotherm which relates the solution concentration to the surface concentration according to Eq. (70),

$$C_a = aC^{1/x} \quad (70)$$

where C_a is the surface concentration and C is the bulk solution concentration of active developer components. Thus if the rate of development is proportional to the concentration of adsorbed species it will deviate from simple integral reaction order and become fractional order as surface coverage increases. Other adsorption isotherms such as that of Langmuir might also be applied.

Electrochemical mechanisms of development have received considerable attention and support in the last 40 years and are generally regarded as the best means of

describing a complex phenomenon. There have been many models proposed and although none of them is complete in its description, considerable progress has been made in understanding both chemical and physical development.

The Gurney–Mott theory [97] of chemical development is based on a short-circuited local cell where the latent image acts as an anode for the developer half-cell and as a cathode for the silver ion half-cell reactions. The developer reacts at the solution/latent image interface (Eq. (71)) and silver ion reacts at the latent image/silver halide interface (Eq. (72)):

where the silver ion source is solid silver halide AgX, and $(\text{Ag})_n$ represents the latent image. This mechanism has been treated quantitatively [100]. Berg [103] suggested an electrochemical mechanism similar to that of Gurney and Mott. Bagdasaryan [104] proposed an electrochemical mechanism assuming that the anodic process is rate-limiting and that the silver has the potential of the silver/silver ion couple.

Pontius, Willis, and co-workers [105] measured the induction times for several developer types and found a correlation between them and the half-wave potential of the developer

$$\log k_i = 1.94 + 6.9E_{1/2} \quad (73)$$

for development by *p*-phenylenediamines and *p*-aminophenols, according to Eq. (73), where k_i is the rate constant for the induction period.

Hoffman and Friedman [106] proposed a mechanism for the induction time in development based on heterogeneous electrochemical theories of corrosion. The model explains the empirical relation derived by Pontius and Willis. In this case the two half-cell reactions of silver and developer give rise to a mixed or corrosion potential, E_{corr} , which if electron transfer is rate-limiting can be described by Eq. (74),

$$E_{\text{corr}} = \frac{1}{2}[E_{\text{D}}^{\circ} + E_{\text{Ag}}^{\circ}] + \frac{1}{2}\beta \ln \frac{k_{\text{Ag}}^0 A_{\text{Ag}} [\text{Ag}^+]}{k_{\text{D}}^0 [\text{D}] A_{\text{D}}} \quad (74)$$

where k_{Ag}^0 = the heterogeneous rate constant for the cathodic process, k_{D}^0 = the heterogeneous rate constant for the anodic process, $[\text{Ag}^+]$ = concentration of silver ion, $[\text{D}]$ = concentration of developer, A_{Ag} = cathodic surface area, A_{D} = anodic surface area, E_{D}° = the formal potential of the developer couple, and E_{Ag}° = the formal potential of the silver couple.

On the basis of further assumptions they arrived at Eq. (75),

$$E_{\text{D}}^{\circ} \equiv E_{1/2} = E' + \beta \ln \frac{k_{\text{D}}^0}{k_{\text{Ag}}^0} \quad (75)$$

which is formally similar to the empirical relation of Pontius and Willis, where:

$$E' = 2E_{\text{corr}} - E_{\text{Ag}}^{\circ} - \beta \ln \frac{A_{\text{Ag}}[\text{Ag}^+]}{A_{\text{D}}[\text{D}]} \quad (76)$$

Pontius and Willis [107] formulated a rate equation (Eq. (77)) for the early stages of chemical development of a single grain, which describes the growth of the latent image during the induction period and the subsequent filamentary growth:

$$\frac{d\text{Ag}}{dt} = k_f^0[\text{R}]S \exp\left(\alpha nF \frac{\Delta E}{RT}\right) - k_b^0[\text{O}]S \exp\left((1 - \alpha)nF \frac{\Delta E}{RT}\right) \quad (77)$$

where k_f^0 is a rate constant for the forward reaction, k_b^0 is a rate constant for the backward reaction, $[\text{R}]$ is the concentration of the reduced form of the developing agent, $[\text{O}]$ is the concentration of the oxidized form of the developing agent, S is the surface area of the silver in contact with the solution, α is the symmetry factor (this is the portion of the potential between the solution and the silver which favors the forward reaction), n is the number of electrons transferred per molecule of R or O and ΔE is the overpotential between the silver surface and the solution. Since the concentration of R far exceeds that of O , the reverse reaction can be neglected so that the rate is described by the first term in Eq. (77). The assumptions made are:

- 1) that electron transfer from the developing agent in solution to the silver surface is the rate-determining step, and
- 2) that there is always an adequate supply of silver ions in the grain to accommodate every electron transfer.

This implies that the latent image has the potential of the silver half-cell and so the overpotential ΔE is the difference between the potentials of the silver and developer half-cells (Eq. (78)).

$$\Delta E = E_{\text{Ag}^0/\text{Ag}^+} + \frac{RT}{nF} \ln[\text{Ag}^+] - E_{\text{R/O}} - \frac{RT}{nF} \ln \frac{[\text{O}]}{[\text{R}]} \quad (78)$$

If this is substituted in Eq. (77) the silver ion concentration has its influence by changing the overpotential via the exponential term. The silver ion concentration is that at the silver/solution interface, not that inside the grain.

The overall rate equation predicts that:

- 1) the rate of growth of the development center is proportional to its surface area;
- 2) it is first order in developer concentration;
- 3) $\log k$ should be proportional to $\log(1/[\text{Br}])$.

These predictions are confirmed for development by ascorbic acid (Figures 26 and 27).

In Figure 28 a summary of the general observations on the exposure, nucleation, detection, growth, and amplification of the latent image is shown.

Figure 26. Dependence of the specific rate constant upon developing agent (ascorbic acid) concentration [107].

Brown and Tong [108] proposed an electrochemical model for the development of a single silver halide grain in which it is assumed that:

- 1) equilibrium exists at the surface of the development site and mass transport to and from that surface is the rate-controlling step;
- 2) silver ion supply through the grain is not rate-limiting;
- 3) the latent image speck does not change in surface area.

The developing silver speck can be regarded as a dual electrode which acts for the developer as an anode and for silver ions as a cathode. A mixed potential E_m is produced by a net flow of electrons from the anode site, where developer is oxidized, to the cathode site, where interstitial silver ion is reduced. The anode potential becomes more positive as oxidized developer is formed and the cathode potential becomes more negative as halide ions are produced at the electrode. It is assumed that the mixed potential of the nucleus E_m is governed by the equilibrium potentials of the two half-cell reactions. This means that the heterogeneous half-cell reactions are fast enough to maintain equilibrium or Nernstian behavior. The supply of silver ions diffusing through the silver halide is considered to be adequate at all times. The model is chosen to represent the point in time when the developing nucleus is still spherical, i.e., before filamentary growth. The assumption made is

Figure 27. Dependence of specific rate constant for pre-filamentary center growth upon bromide ion concentration, showing conformity with the Butler–Volmer law of electrode kinetics. Developing agent, 10^{-2} M ascorbic acid [107].

that the area of the nucleus is constant and so the model is time-independent and does not describe the autocatalytic nature of the development process.

Mass transport of developer to, and oxidized developer and halide ions from, the silver speck is calculated by the method of spherical diffusion. The surface concentrations of the active species are then used in the Nernst equation to calculate E_m , the surface potential of the developing nucleus. The rate equation (79) obtained is:

$$1000W = \frac{4\pi aR^*D_R(1 + \lambda a)}{(1 + \lambda a) + \frac{D_R}{D_Q} \exp \left[\frac{-nF}{RT} (E_{\text{AgX}}^\circ + E_\eta - E_{1/2}^{\text{Dev}}) \right]} \left[X^* + \frac{1000nW}{4\pi bD_X} \right]^n \quad (79)$$

where R^* = is the initial concentration of reduced species, X^* = initial bulk halide

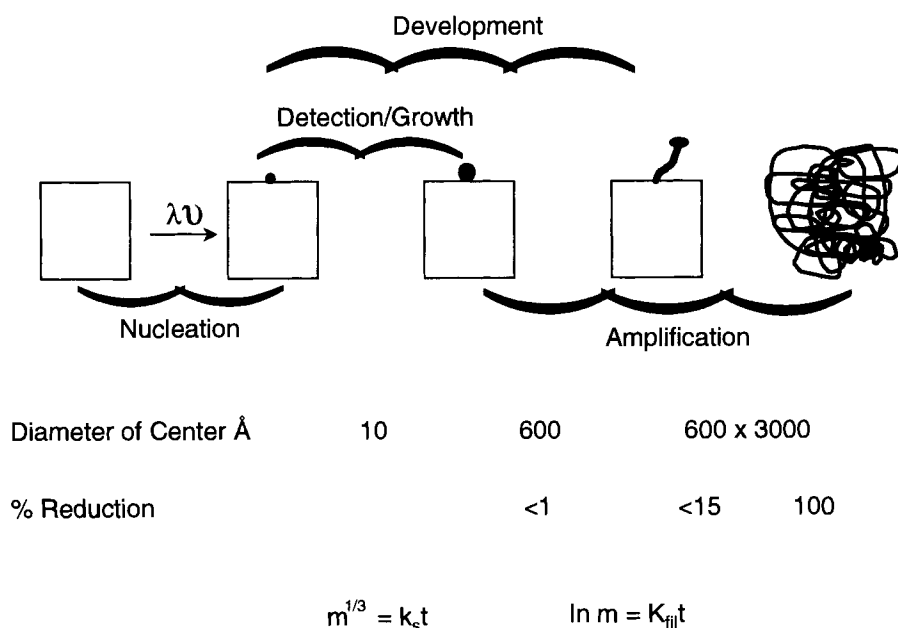

Figure 28. Kinetic aspects of development.

concentration, W = is the development rate in mol s^{-1} (1000 converts mol cm^{-3} to mol L^{-1}), D_R = diffusion coefficient for the reduced developer [$\text{cm}^2 \text{s}^{-1}$], D_Q = diffusion coefficient for the oxidized developer [$\text{cm}^2 \text{s}^{-1}$], D_X = diffusion coefficient of halide [$\text{cm}^2 \text{s}^{-1}$], a = radius of developing nucleus [cm], b = radius of the silver halide grain [cm], $\lambda = (k/D_Q)^{1/2}$, k = summation of all pseudo first-order decompositions of oxidized developer [s^{-1}], E_{AgX}° = the standard potential for a silver electrode in unit activity of halide ion, $E_{1/2}^{\text{Dev}}$ = the half-wave potential for the developing agent, E_η = an overpotential term to correct for the different silver potential of small particles compared with bulk silver.

There are some limiting cases of the complete equation.

- 1) When the rate is determined solely by the diffusion of reduced developer, it becomes:

$$1000W = 4\pi a D_R R^* \quad (80)$$

Here the rate is linear in developer concentration but independent of developer potential, halide ion concentration and rate of scavenging of oxidized developer. Such cases have not been seen experimentally.

- 2) When the second denominator is much larger than the first and the overall halide concentration is nearly equal to the bulk level (this occurs at very low developer concentrations), Eq. (79) becomes:

$$1000W = \frac{4\pi aR^*D_Q(1 + \lambda a)}{\exp \frac{-nF}{RT} \left\{ E_{AgX}^\circ + E_\eta - E_{1/2}^{Dev} - \frac{RT}{F} \ln(X^*) \right\}} \quad (81)$$

Here the rate is first-order in developer concentration and has the expected potential dependence.

- 3) This occurs when the second term in the denominator is larger than the first term and the rate is also large:

$$1000W = \frac{4\pi aD_Q(1 + \lambda a)R^*}{(1000n/4\pi bD_X)^n \exp \frac{-nF}{RT} (E_{AgX}^\circ + E_\eta - E_{1/2}^{Dev})} \quad (82)$$

When this applies the rate is proportional to the developer concentration to the $1/(n+1)$ th power. Such dependencies have been observed in practice for several developing agents.

A review of electrochemical models of development has been given by Sahyun [109] in which selectivity is treated in terms of the Marcus and Gerischer [110] theories of electron transfer.

Shiao and Dedio [111] formulated an electrochemical model of development which used the same diffusion calculations of Brown and Tong but included a term for the increasing surface area of the growing speck. Numerical methods were used to provide solutions to the equations and the rates of development of ascorbic acid and 4-methyl-4-hydroxymethyl-1-phenyl-3-pyrazolidone (MHP) were modeled in fair agreement with experiment. The important features treated by the model include the redox potential of the developing agent, the overpotential, diffusion and adsorption of developing agents, halide ions, and oxidized developing agents, and the inhibition of development by oxidized developing agent and halide ions.

Many of the electrode theories have assumed that the anodic reaction is rate-limiting and that the cathodic reduction of silver ions from silver halide is not rate-limiting and might not present any limitations to the process of development. Hamano et al. [112] contend that there are instances where the cathodic process does influence development. They use the Butler-Volmer equation as the basis for their development rate model and derive Eq. (83),

$$\frac{dm_i}{dt} = 2\pi r_i^2 M \frac{J}{F} \left\{ \exp \left[\frac{\alpha nF}{RT} \left(E_{AgBr} - E_{redox} - \delta E - \frac{0.85 \times 10^{-8}}{r_i} \right) \right] - \exp \left[\frac{-(1-\alpha)nF}{RT} \left(E_{AgBr} - E_{redox} - \delta E - \frac{0.85 \times 10^{-8}}{r_i} \right) \right] \right\} \quad (83)$$

where J = development current density, m_i = mass of the development center, M = atomic weight of silver, S = surface area of the development center in contact with the developer, E_{AgBr} = potential of silver in contact with a large silver particle, E_{redox} = potential of the developer, r_i = the reduced radius of the spherical center

starting from a latent image of i atoms, δE = reduction in overpotential used to calculate the development current from the observed development current–potential curve, $0.85 \times 10^{-8}/r_i$ = correction of the silver potential for small particles.

These workers demonstrate that the cathodic process is important in the effect of benzotriazole antifoggants on the development rate. These materials retard the development rate by ascorbic acid but do not adsorb to metallic silver, whereas they do adsorb to silver halide. In this sense benzotriazoles should not influence the anodic process, but might influence the cathodic process.

Hamano et al. [112a] extended their electrode model to include superadditivity and the effects of halide ions and quaternary salts on development.

Friedrich and Eilers [113] have proposed a corrosion model of development and derived electron transfer equations based on the Butler–Volmer expression which can be simplified into three cases. Case 1 is when both the forward and reverse processes of developer oxidation are important. Case 2 is when the net rate is limited by the forward rate of developer oxidation. Case 3 corresponds to a rate which is limited by the kinetics of both developer oxidation and silver halide reduction.

Boyack [114] has used an electrode theory of development to derive characteristic curves of photographic development and its temperature dependence. The conclusions indicate that:

- 1) at constant temperature changes in development conditions should only cause an expansion or contraction of the time scale;
- 2) the apparent activation energy depends on the potential difference between the developer and silver/silver halide potentials;
- 3) the activation energy varies with latent image size.

The single-grain model was extended by use of grain size distributions to give the mass fraction developed as a function of exposure.

Shiao and Bistrovich [115] added the ability to model physical development to the original chemical development model of Shiao and Dedio, and included inhibition by iodide released during development. Also, unlike the model of Pontius and Willis, certain cases where the cathodic process can be the rate-limiting step are identified. The model is able to describe the silver development kinetics of liquid emulsions and in coated layers using E-6 first developer.

1.2.3 Coupling

The useful reaction of oxidized *p*-phenylenediamines is to generate dye. They can react with an electron-rich species, a coupler anion, to form a leuco dye which either oxidizes or loses a fragment to form the dye. As an example, oxidized *p*-phenylenediamine can react with a phenol to form a cyan dye as shown in Scheme 2. The leuco dye oxidation usually takes place with the consumption of another molecule of CDox, which is reduced back to the color developer. Thus production of a molecule of dye by this route uses two molecules of CDox or four silver ions and is known as a four-equivalent reaction. Dye formation can proceed by a two-equivalent route if there is a good leaving group such as a chlorine atom at the reaction site on the coupler anion.

Scheme 2. Cyan dye formation from *p*-phenylenediamines.

The color of the dye produced is determined by the structure of the coupler. In general the dye produced in a particular photographic layer is complementary to the sensitization of the emulsion in that layer, i.e., cyan dye is produced in layers containing red-light-sensitive emulsions, magenta dye is produced in layers containing green-light-sensitive emulsions and yellow dye is produced in layers containing blue-light-sensitive emulsions. A good, detailed description of this process can be found elsewhere [116].

Examples of some coupler structures are shown in Figure 29.

1.3 Bleaching/Bleach-Fixing

1.3.1 Introduction—General Mechanisms

In color chromogenic photographic systems, silver is generated along with the dye. This silver desaturates the color and generally has to be removed. The removal

**cyan dye forming****yellow dye forming****magenta dye forming****Figure 29.** Some coupler structures: *, position at which coupling with CD-ox occurs.

process must take out the silver but retain the dyes unharmed. A typical process is Kodak Process C-41, shown earlier in Table 1.

There is also a requirement for the removal of silver in some black-and-white processes. In the case of black-and-white reversal processing the initially imagewise exposed silver is removed before the second development stage. An example of a process might be as shown in Table 7 [117].

Table 7. A typical black-and-white reversal process.

Process step	Time [s]
Develop	120
Rinse	30
Bleach	50
Rinse	30
Clear	30
Rinse	30
Re-expose	
Re-develop	50
Rinse	30
Fix	50
Wash	120
Dry	

Bleaches are sometimes used to reduce the density of black-and-white images by removing silver, in solutions that are confusingly known as “reducers”. These bleaches can be solvent bleaches, where the oxidized silver dissolves in the bleach, essentially without complexation. Alternatively they can contain a silver complexing agent and act as a bleach–fix.

In this section we shall discuss bleaches in detail. The first part will deal with general kinetics related to bleaches and the later parts will deal with specific types of bleaches that are currently in use and will discuss their deviation from the expected behavior.

The process of bleaching is the reversal of development, i.e., it is the conversion of silver metal back to silver ions (Eq. (84)).

The bleaching reaction is controlled thermodynamically and kinetically. For the reaction to take place it must be thermodynamically favorable and also kinetically possible. We shall see that there are some bleaching agents for which the bleaching reaction is strongly favorable but the reaction is hindered and catalysts are necessary for them to be useful. The kinetics are also dependent on the movement of the bleaching agents and other solution components to and from the reaction site through swollen gelatin.

The thermodynamics of the reaction can be considered from the point of view of the silver grain being an electrode in the same way as it might be considered for developers. The potential of the redox couple of the bleaching agent can be written as Eq. (85),

$$E_{\text{Red/Ox}} = E_{\text{Red/Ox}}^\circ + (RT/zF) \ln([\text{Ox}]/[\text{Red}]) \quad (85)$$

where z is the number of electrons transferred by the bleaching agent, and that of the silver grain as Eq. (86).

$$E_{\text{Ag/Ag}^+} = E_{\text{Ag/Ag}^+}^\circ + (RT/F) \ln[\text{Ag}^+] \quad (86)$$

The reaction will proceed to bleach the silver if the redox couple potential is more positive than that of the silver. If it is not, the reaction may reverse and we have development.

1.3.2 Solvent Bleaches

The silver electrode potential is influenced by the constitution of the bleach solution. The high value of the standard redox potential of silver ($E_{\text{Ag/Ag}^+}^\circ = 0.799$ V vs. NHE) demands strong oxidants for an irreversible oxidation of silver. The types of bleach working in this way are known as solvent bleaches. The silver is oxidized and then dissolves in the bleach. This type of bleach is almost exclusively reserved

Table 8. Electrode potentials of some bleaching agents.

Bleaching agent	System	E° (vs. NHE) at 25°C [mV]
Persulfate	$\text{S}_2\text{O}_8^{2-} + 2\text{e}^- \leftrightarrow 2\text{SO}_4^{2-}$	~2.00
Permanganate	$\text{MnO}_4^- + 4\text{H}^+ + 3\text{e}^- \leftrightarrow \text{MnO}_2 + 2\text{H}_2\text{O}$	1.65 – 0.079 pH
Hydrogen peroxide	$\text{H}_2\text{O}_2 + 2\text{H}^+ + 2\text{e}^- \leftrightarrow 2\text{H}_2\text{O}$	1.36 (1.0 M at pH 7.0)
Dichromate	$\text{Cr}_2\text{O}_7^{2-} + 14\text{H}^+ + 6\text{e}^- \leftrightarrow 2\text{Cr}^{3+} + 7\text{H}_2\text{O}$	1.33 – 0.138 pH
Iron	$\text{Fe}^{3+} + \text{e}^- \leftrightarrow \text{Fe}^{2+}$	0.77
Hexacyanoferrate	$\text{Fe}(\text{CN})_6^{3-} + \text{e}^- \leftrightarrow \text{Fe}(\text{CN})_6^{4-}$	0.46
Iron EDTA	$\text{FeEDTA}^- + \text{e}^- \leftrightarrow \text{FeEDTA}^{2-}$	0.117

for the reversal black-and-white process, where the developed silver has to be removed from the film before the second development; see Table 7.

There is a range of oxidants that are currently used as bleaching agents. They have a wide range of oxidising potential (Table 8).

As can be seen by inspection, there are only a few oxidising agents that are likely to be suitable for making a solvent bleach: dichromate, permanganate, persulfate and hydrogen peroxide. The last two in the list are very poor bleaching agents as their oxidation appears to be kinetically hindered. They can only be used in the presence of a suitable catalyst, which will be described later.

The bleaching agent is chosen for use depending on the process, ease of use, environmental considerations, and cost. Some of these points will become more apparent in the sections dealing with particular types of bleach.

The bleaching reaction is dynamic and the electrode potentials are dependent on the concentration of ions at the silver grain surface. As the reaction proceeds, silver ions build up at the surface and the silver electrode potential rises. The silver electrons diffuse away, through gelatin to the bulk bleach solution. Similarly, the bleaching agent has to diffuse to the silver surface where it is reduced. The reduced species lowers the oxidant's potential and it must diffuse away for the reaction to proceed. The solvent bleaching reaction is thus controlled by the potentials and the diffusion of species through the photographic layers. For a diagrammatic representation of the bleaching of one grain in a photographic layer, see Figure 30.

However, if the silver ion concentration is kept low in another way, the silver potential is low and less powerful oxidants can be used for bleaching. The silver ion concentration can be reduced by precipitation with halide ions (Eq. (87)).

This gives a rehalogenating bleach. Rehalogenating bleaches usually contain oxidants with lower electrode potentials.

The silver halide formed can then be dissolved and removed in a later fixing step. Alternatively the silver ion can be complexed, usually to form a water-soluble species, which washes out of the gelatin. This gives the process step known as a bleach-fix as it combines both steps. The potential of the silver electrode in a

Figure 30. The bleaching process.

halide solution can be written as Eq. (88),

$$E_{\text{Ag}/\text{Ag}^+} = E_{\text{Ag}/\text{Ag}^+}^{\circ} + (RT/F) \ln(\text{SP}/[\text{X}^-]) \quad (88)$$

where SP is the solubility product of the silver halide, or using the silver halide electrode potential:

$$E_{\text{Ag}/\text{Ag}^+} = E_{\text{Ag}/\text{AgX}}^{\circ} - (RT/F) \ln[\text{X}^-] \quad (89)$$

The solubility products of the halides are shown in Table 9. By inspection we see that iodide reduces the silver potential to the lowest point at the same concentration. In practice bromide is usually used, as the silver bromide formed is more readily dissolved in the subsequent fixing step. The concentration of halide at the bleaching site is also influenced by the reaction and the diffusion of halide to the surface of the bleaching grain. Nickel et al. [118] have investigated the bleaching reaction electrochemically, removing the electrons from the silver in a cell by applying a potential to a rotating silver disk electrode electrically. They determined the influence of the halide ions and point out that in this case only halide ions have to pass through the solution/solid boundary. They measured both the rate of formation of silver halide and the rate of reduction of bleaching agents at this electrode.

Table 9. Solubilities of silver halides.

Halide	Solubility product, SP, in water at 25°C
Silver chloride	1.6×10^{-10}
Silver bromide	7.7×10^{-13}
Silver iodide	1.5×10^{-16}

Figure 31. Redox potential diagram showing mixed potentials for bleaching.

They measured the zero potential point of the system, which depends on the halide concentration and type as described by the equations above. They were able to measure the effect of diffusion of species to the electrode and were able to determine a mixed potential of the electrode where the forward transfer of electrons from the silver was equal to the rate of reduction of the oxidant. This is shown diagrammatically in Figure 31. Nickel et al. found that the adsorption of halide to the silver surface did not influence the potential if the halide layer was less than 5 μm thick, but they did note that at a clean silver surface the silver halide formation began at a higher potential than expected, which they attributed to the high solubility of microscopic silver on the surface.

However, Matsuo et al. [119] found that the halide on the surface of a silver plate reduced the rate of bleaching. The amount of bleaching with time was determined at different temperatures for a number of different bleaches. All the bleaches showed the same characteristic curve shape, which was largely independent of the halide concentration. By way of example, Figure 32 shows data for an iron(III) EDTA/bromide bleach. Plotted also on the graphs are the expected gradients if the rate of bleaching is proportional to the inverse of the depth of silver halide ($\gamma = 1/2$) or if the rate is proportional to the inverse square of the halide thickness ($\gamma = 1/3$). From the log-log plots of these curves it was deduced that the rate was determined by the rate of migration of species through the silver halide. Matsuo et al. suggested that it was the silver ions or electrons that migrated through the silver lattice. The results also showed that the potential of the oxidant had only a small effect on the rate of bleaching of a silver sheet.

Similarly Fyson and Levenson [120] showed that the rate of bleaching of silver was hindered by the silver halide on the surface in much the same way. However, they found that the rate of bleaching in a hexacyanoferrate(III) bleach was depen-

Figure 32. Rate kinetics of rehalogenating bleaching.

dent on the halide concentration, where there was an optimum halide concentration for the extent of bleaching; see Figure 33. It appears that this maximum rate corresponds to the minimum solubility of silver bromide [121] in bromide solutions. However, this does not correspond to the minimum concentration of silver ion because at high bromide concentrations the silver ions are further complexed with halide ions to form complex species, further reducing the silver ion concentration. Electron micrographs of the bleached surface showed that the bleaching had not taken place evenly (Figure 34).

Observations of silver halide crystals formed by bleaching [122] in different halide concentrations, as shown in Figure 35, suggested that the silver halide was mobile during bleaching and that recrystallization could occur. This process could be likened to the Ostwald ripening [123] that takes place during the precipitation of silver halide to make the original photographic emulsion. At high bromide the silver becomes more soluble due to the formation of complex species AgBr_2^- , AgBr_3^{2-} , and can diffuse to make thermodynamically more stable large crystals. It is possible that silver halide at high bromide concentrations might cause a more continuous layer of silver halide to form over the bleaching crystal but this has yet to be demonstrated.

Matsuo did point out that because silver normally develops to give filamentary silver [119, 124], this is much more easily bleached than a mass of silver. He demonstrated the difference in the rate of bleaching a developed silver grain as compared with a silver surface. This implies that the means by which the silver is developed determines the bleaching rate. Silver that has been developed in a developer

Figure 33. Effect of halide concentration on rate of bleaching with hexacyanoferrate(III).

Figure 34. Electron micrograph of bleached silver sheet.

Figure 35. Effect of bleach halide concentration [M] on structure of bleached grains: (a) Original grains; (b) Developed and Final grains; (c) 10g/l KBr; (d) 50 g/l KBr; (e) 100 g/l KBr.

with a large amount of physical development, and therefore more massive silver speck, might be expected to bleach more slowly than a totally chemically developed filamentary speck.

Fyson [125] showed that the potential of the oxidant did affect the extent of bleaching of large, developed silver grains in a photographic layer (Figure 36). The greater the bleach potential, the more silver was bleached and the smaller was the effect of the halide coating of the grain surface.

1.3.3 Bleach-Fixes

There are other ways to decrease the silver ion activity in the bleaching system to allow the oxidation of silver to proceed. The silver ions can be complexed. An expression relating silver complexation to potential can be written. If the silver forms a complex with n ligand molecules, it has form of Eq. (90):

$$E_{\text{Ag}/\text{Ag}^+} = E_{\text{Ag}/\text{Ag}^+}^{\circ} - n(RT/F) \ln \beta[\text{L}^-] \quad (90)$$

where β is the cumulative stability constant of the complex of ligand L and where

Figure 36. Effect of bleach potential on bleaching efficacy. The lower the residual density the more efficacious the bleach.

there is little mono-ligand complexation. A bleach containing a complexing agent is usually known as a bleach-fix, or blix. Matsuo et al. showed [119] that the rate of bleach-fixing was almost constant after an initial, more rapid reaction (Figure 37). The results are shown for a number of different silver complexing agents. It is believed that in the initial phase, the reaction is reaching a constant rate while the silver ion concentration equilibrates. The rate of formation of silver oxidation products equilibrates with diffusion away from the reaction site of the silver complexes. This steady state is quickly set up. The results also indicate that, at least at high concentration levels, the type of the complexing agent is not very significant.

Figure 37. Effect of silver complexing agent on bleaching rate [119].

Matsuo et al. also found that at concentrations exceeding 0.8 M thiosulfate, the rate of bleach–fixing was almost independent of thiosulfate concentration.

Care has to be taken with the choice of bleaching agent and complexing agent in bleach–fixes. The fixing agent is usually thiosulfate, which itself is a reducing agent. The bleaching agent has to be chosen so that it will not oxidize the fixing agent but has sufficient oxidation potential to oxidize silver. Thiosulfate has a very high stability constant with silver ions, and so the silver ion concentration at the bleaching site is reduced, lowering the silver/silver ion potential and thus reducing the constraint on the bleaching agent. Most long-lasting practical bleach–fixes use iron(III) complexes as oxidizing agents. Choice of the ligand and solution pH allows fine tuning of the oxidizing potential so that bleaching is rapid and decomposition of the thiosulfate is slow [126].

1.3.4 Diffusion

The potential of the redox couple is governed by the concentration of oxidizing and reducing species at the reaction site. With a rotating disk electrode, Nickel et al. [118] found that the redox couple was quickly established at the surface of the silver for iron complex systems and that the rate of reaction was almost entirely dependent on the diffusion rate of the oxidized and reduced species to and from the surface. In a photographic system, developed silver grains that are to be bleached are suspended in swollen gelatin in the photographic layer. In order to maintain the electrode potential at the bleaching silver grain, oxidized species must diffuse to it and reduced species diffuse away from it through the gelatin. The rate of diffusion of these species through gelatin is therefore important. Matsuo [127] and Fyson [125] have investigated the diffusion of some bleaching agents through gelatin. In the manufacturing process coated gelatin is usually hardened so that it is more robust, can be processed at higher temperature [128], and is more scratch-resistant. The hardening, which involves crosslinking the long gelatin chains, reduces the ability of the gelatin to swell when it is put into water. This “swellability” influences the diffusion rate of species through the gelatin as the diffusing molecules have to avoid the gelatin chains. It also restricts the distances that species have to travel through the gelatin. There is an optimum swell of the photographic layer which gives the fastest process in diffusion-controlled systems [129].

Both Fyson [125] and Matsuo [127] measured the diffusion coefficients in gelatins that had been treated with different amounts of hardener and therefore had different swellability. Fyson found that the diffusion coefficient in gelatin, D_{gel} , could be related to the diffusion coefficient in water, D_{water} , and the swelled to dry thickness ratio, Z , of the hardened gelatin. The empirical relationship was found to be Eq. (91).

$$D_{\text{gel}} = D_{\text{water}} \exp[-7/(Z + 0.7)] \quad (91)$$

This could be rationalized in terms of reactive species having to “squeeze” their way through the gelatin polymer strains, and could be related to Cohen and Turnball’s

Table 10. Diffusion coefficients of some bleaching agents.

Bleaching agent	Diffusion coefficient in water at 21 °C [$\text{cm}^2 \text{s}^{-1} \times 10^6$]
Potassium hexacyanoferrate(III)	7.5
Copper(II) sulfate	11.0
Sodium iron(III) ethylenediamine tetraacetic acid complex	4.2
Sodium iron(III) iminodiacetic acid complex	3.2
Sodium iron(III) nitrilotriacetic acid complex	3.5
Sodium iron(III) methyliminodiacetic acid complex	4.8
Iron(III) chloride	5.2
Potassium dichromate	5.0

relationship [130] for the movement of hard spherical particles through holes in the polymer matrix. From the experimental results the diffusion coefficients in water were determined (Table 10).

1.3.5 Specific Bleaching Agents

Dichromate

Bleaching based on dichromate as the oxidant has been used extensively in the past and is useful for providing solvent bleaches as the dichromate has sufficient potential (see Table 10) without the need to add halide or a silver complexing agent. Solvent bleaches are especially useful for black-and-white reversal systems where they are still used extensively.

Dichromate bleaches have the property of hardening the gelatin [131] due to the formation of chromium(III) ions that form strong complexes with the gelatin strands similarly to aluminum. It is for this reason that dichromate bleaches have found use in making phase holograms [132], which rely on the different refractive indices of hard and soft gelatin. The hologram is exposed and developed. It is then bleached in a dichromate bleach, which leaves an image of hard and soft gelatin. The soft gelatin may be washed off in warm water.

As can be seen from Eq. (92), the system is very sensitive to hydrogen ions, and dichromate bleaches are always acid, usually having sulfuric acid as the buffer. The sulfate ion does not bind with the silver ion; therefore the silver ion retains its solubility and can diffuse away from the reaction site.

The use of dichromate bleaches in general has declined. Chromium(VI) is considered to be very toxic and its discharge to sewers is severely restricted in many countries [133]. The use of a dichromate bleach would have to be accompanied by

measures at the processing plant to prevent the discharge of chromium(VI), and this is not considered economic.

Iron(III) complexes

The most widely used bleach until the 1970s was hexacyanoferrate(III): ferricyanides, as such compounds were more commonly known, were inexpensive and readily available. They gave bleaches that were pH-insensitive but required a halide to be present so as to reduce the silver potential below that of the bleaching agent (see Table 8). They also gave bleaches that were strong enough to oxidize any leuco dye that might have been formed in the developer (see Section 1.2.3). The potential of the hexacyanoferrate(III) ion is sufficient to oxidize color developer that might be carried into the bleach from a previous step in the process. If this were to happen, the color developer would be oxidized and couple indiscriminately with any ionized coupler that was available, giving an overall undesirable coloration, or "stain", to the film. For this reason there is always at least one bath or wash between a color developer and hexacyanoferrate(III) bleach. There are regulations in some countries on the discharge to sewer of hexacyanoferrate(III), most for fear of the material coming into contact with a strong acid and liberating toxic hydrogen cyanide. This problem is somewhat alleviated by oxidizing the waste hexacyanoferrate(II) (ferricyanide) at the processing site with either ozone or persulfate, and recovering the ferricyanide for reuse.

Iron(III) chloride is used as a bleaching agent in some commercial processes as it is a powerful oxidant. It has to be used in acid solution to ensure that there is no precipitation of hydroxy species or reaction of the hexaaquo iron(III) ion with the gelatin to form a highly colored species that stains the gelatin. This stain is difficult to remove and relies on there being powerful iron complexing agents, such as citrate, in subsequent baths.

By far the most commonly used bleaching agents are aminocarboxylate complexes of iron(III). The potential of a simple iron complex redox system can be written as Eq. (93),

$$E_{\text{Fe(III)/Fe(II)}} = E_{\text{Fe(III)/Fe(II)}}^{\circ} + (RT/F) \ln \frac{[\text{Fe(III)}]}{[\text{Fe(II)}]} - \frac{n_{\text{Fe(III)}}}{n_{\text{Fe(II)}}} (RT/F) \ln \frac{\beta_{\text{Fe(III)}}}{\beta_{\text{Fe(II)}}} [\text{L}^-] \quad (93)$$

where $n_{\text{Fe(III)}}$ and $n_{\text{Fe(II)}}$ are the numbers of complexing agent molecules per iron(III) and iron(II) respectively and $\beta_{\text{Fe(III)}}$ and $\beta_{\text{Fe(II)}}$ are the cumulative complexing coefficients of the complexing agent with the respective iron species. By inspection of the formula it can be seen that by choosing complexing agents of different complexing coefficients, the iron redox potential can be modified to suit an application.

This equation is very much simplified, as there are other reactions of the complex or the ligands that affect the potential. For instance, ethylenediaminetetraacetic acid

(EDTA) is a favorite ligand as it is relatively inexpensive, it is nontoxic, and it readily forms stable iron complexes with a useful redox potential. The concentration of the fully ionized ligand is determined by the four ionization constants of the EDTA free acid. The iron complex also has a vacant ligand site that can pick up a hydroxyl ion and therefore has a further complexing constant for the hydroxy species. It has also been observed that this hydroxy species can react with another to form a dimer, altogether making a complex system. The potential for this system with excess EDTA can be described by Eq. (94), a modified version Eq. (93), taking into account the other equilibrium constants:

$$E_{\text{Fe(III)/Fe(II)}} = E_{\text{Fe(III)/Fe(II)}}^{\circ} + (RT/F) \ln \frac{[\text{Fe(III)}]}{[\text{Fe(II)}]} - (RT/F) \ln \frac{\beta_{\text{Fe(III)}}}{\beta_{\text{Fe(II)}}} \alpha [\text{L}]$$

$$\times \frac{[\text{H}^+]^2 + K_1^{\text{Fe(III)}} [\text{H}^+] + K_1^{\text{Fe(III)}} K_2^{\text{Fe(III)}} + 2K_D K_1^{\text{Fe(III)2}} [\text{Fe(III)}]}{[\text{H}^+]^2 + K_1^{\text{Fe(II)}} [\text{H}^+] + K_1^{\text{Fe(II)}} K_2^{\text{Fe(II)}}} \quad (94)$$

where $K_1^{\text{Fe}(n)}$, $K_2^{\text{Fe}(n)}$ are the ionization constants of the respective iron complexes, K_D is the dimerization constant of the iron(III) hydroxy-EDTA complex, and α is the relative concentration of the fully ionized ligand of EDTA and can be described by Eq. (95),

$$\alpha = \frac{K_1 K_2 K_3 K_4}{[\text{H}^+]^4 + K_1 [\text{H}^+]^3 + K_1 K_2 [\text{H}^+]^2 + K_1 K_2 K_3 [\text{H}^+] + K_1 K_2 K_3 K_4} \quad (95)$$

where K_1 , K_2 , K_3 , K_4 are the ionization constants of EDTA.

If the various constants are known, the potential can be determined. Brown [134] has made this determination and the results are shown for two iron concentrations in Figure 38. The redox potential between pH 4 and 6 is 117 mV (NHE) and is such that a bleach made with this oxidizing agent can immediately follow a developer with little risk of the developer being oxidized and subsequently forming unwanted dye. For example, CD3 has a half-wave potential of 0.399 V (NHE) at pH 5. Assuming Nernstian behavior, it can be shown that the proportion of developer oxidized in the bleach is governed by Eq. (96).

$$RT \ln \frac{[\text{CDox}]}{[\text{CD}]} = -0.282 + RT \ln \frac{[\text{Fe(III)}]}{[\text{Fe(II)}]} \quad (96)$$

If a bleach is about 90 % iron(III) in operation, we would only expect about 0.02 % of the developer to be oxidized and usually this is insufficient to form unwanted dye, especially as at pH 5 most of the coupler in film would not be ionized and therefore would not couple.

With a potential of 117 mV (NHE), iron(II) species are readily oxidized by air, which is usually passed through a bleach solution in a processor to regenerate

Figure 38. The effect of iron(III) EDTA dimerization on electrode potential.

iron(III). This oxidation has been extensively studied by Brown and Mazzarella [135].

Other iron complexes with slightly different properties can be used. Iron(III) 1,3-propylenediaminetetracetic acid (PDTA) has largely replaced the EDTA complex in film processes as it has a higher potential (230 mV NHE at pH 5) and bleaches more rapidly. It is used in more acid solution than iron(III) EDTA bleaches and this prevents formation of unwanted oxidized developer. Iron(III) EDTA is still the oxidizing agent of choice in bleach-fixes where the oxidant is mixed with a silver solvent. The potential of iron(III) EDTA is low enough not to oxidize thiosulfate used as the fixing agent. If iron(III) PDTA is used, the solution rapidly decomposes.

With such a low working electrode potential, these bleaches are susceptible to being inhibited by material adsorbed to the silver metal or silver halide surface. After development, sensitizing dye remains on the surface of the metal or unreduced silver halide and this can inhibit bleaching. Matsuo [136] carried out experiments with a number of sensitizing dyes adsorbed onto silver surfaces and found that bleaching by iron(III) EDTA was inhibited by sensitizing dyes with a high heat of adsorption, suggesting that they prevented the passage of electrons from the silver surface. He also discovered that the charge on the dye was important, the negatively charged dyes inhibiting bleaching. He postulated that these were repelling the negatively charged bleaching agent. He also found that with more powerful oxidants such as iron(III) chloride the effect of dyes was not seen.

Persulfate

The rate of attack on silver by powerful oxidizing agents such as persulfate is impeded. Levenson [137] suggested that this is caused by the formation of a skin of silver oxide on the surface of the metal. He produced a simplified diagram from the

Figure 39. Corrosion diagram for silver [138].

data of Vanleughenaghe et al. [138], showing the domains of immunity, corrosion, and passivation for a silver system (Figure 39).

It can be seen that at low pH the oxidation is most likely to occur but the potential of persulfate is always in the passivation region. It was observed by Lumières and Seyewetz [139] that “reduction” of the image density with persulfate had a notable induction period and the reaction appeared to be autocatalytic. It was suggested that silver ions themselves catalyze the reaction. It is possible that the buildup of silver ions lowered the silver potential sufficiently for corrosion to occur; alternatively the production of silver(III) compounds might be responsible for the acceleration.

Persulfate bleaches can be used efficiently, provided a catalyst is present. The catalyst might either be expected to disrupt any layer formation on the surface of the silver or be an electron transfer agent that can act as intermediary for electrons between the silver and persulfate ions.

Willems [140] showed that positively charged onium compounds I–IV (Figure 40) would catalyze persulfate bleaching (Figure 41). He suggested that they worked by reducing the negative charge barrier on the silver or silver halide surface. These compounds were generally positively charged and Willems suggested that for electron transfer to take place, they must be adsorbed to the silver or growing silver halide surface. However, he also found that they tended to slow down bleaching by hexacyanoferrate(III). He suggested that these compounds repelled the positively charged center of the hexacyanoferrate(III) ion. However, this seems unlikely with such a tightly formed species as hexacyanoferrate(III). An alternative explanation

Figure 40. Onium catalysts for persulfate bleaching [140].

Figure 41. Effect of onium catalysts I-IV on bleaching rate in persulfate.

might just be that the onium compound alters the silver electrode potential so that it falls in a region where persulfate or one of its derived radical species can react without passifying the surface.

Willems also showed, in the same article, that some compounds that formed stable radicals would also catalyze silver bleaching by persulfate. He suggested that these compounds acted as electron transfer agents, performing as a shuttle for electrons from the silver to the persulfate; thus a superadditive mechanism, similar to that seen in development, could operate. Kobayashi et al. [141] observed a similar effect with *N,N,N',N'*-tetramethyl-*p*-phenylenediamine but also showed that this compound was destroyed by the action of persulfate, and benzoquinone was formed. It was this quinone that acted as the electron transfer agent in aged solutions.

Hydrogen peroxide

Hydrogen peroxide bleaches are rare, even though they might be expected to be “environmentally friendly” as the by-product of the reaction is water. Figure 42, a diagram of the electrode potential of hydrogen peroxide using the data of Vanleuvenhaghe et al. [138], includes the domains of bleaching or corrosion and decomposition. In order for bleaching to occur, the potential of the silver must be controlled so that it falls in this region. If it falls in the decomposition region oxygen is evolved in the gelatin, destroying its structure, and vesiculation occurs. Even when the electrode potential is controlled so that it falls in the bleaching region, the reaction is quite slow. It appears that the described reaction is kinetically inhibited.

Figure 42. Electrode potential diagram for hydrogen peroxide system.

There have been a number of patents recently that have given reasonable bleaches but none has been employed commercially. The useful peroxide bleaches control the silver electrode potential by complexing the silver [142] or by careful control of the halide concentration [143].

1.3.6 Dye-Bleaches

Bleaching can be carried out by a colored oxidant which is reduced by the silver metal to colorless compounds. This is the basis of the dye-bleach process. The overall reaction may be written as Eq. (97).

The dye-bleach material has at least three layers, one for each color record. Associated with each record is a color-sensitized emulsion and a diazo dye of the complementary color. The material is exposed and then processed as follows:

Black-and-white develop
Dye-bleach
Bleach
Fix
Wash

The imagewise silver negative is formed during the development step. In the dye-bleach the dye coats in the film are bleached where silver is present, and remain in the area where there is no silver. In this way a positive image is built up. Thirtle gives a detailed description of the process [116a].

The process as described above is much simplified. The dyes are usually immobile and therefore cannot reach the developed silver surface. It is therefore necessary to include a water-soluble electron transfer agent, or ETA, in the system. It is also necessary to tie up the silver ion formed to prevent the reverse reaction. This is done by including a halide or a silver-complexing agent such as thiourea in the system. The electron transfer agents are usually quinoxalines, phenazines, or naphthazines [144]. The mechanism for reaction has been extensively studied by Deuschel, Schellenberg, and Gunter and Matejec [145]. It is postulated that the initial reaction is the reduction of the ETA, A, to a dihydro radical, $\bullet\text{AH}_2^+$, that disproportionates to a reactive dihydro derivative, AH_2 . This reactive reduced dihydro derivative reacts with a diazo dye to form colorless products that can be washed from the layer. The reactions can be written as Eqs. (98)–(100).

After the dye-bleach process, any remaining silver is bleached in a conventional bleach, which is followed by a fix to remove silver halide and a wash to remove any residual processing components and dye fragments.

1.3.7 Fixing and Washing

Although fixing and washing are not usually considered as electron transfer reactions, they are important parts of photographic processing as they confer stability to the processed material and will be discussed briefly.

Fixing is the process whereby any remaining light-sensitive silver halide compounds are removed from the developed and possibly bleached material. There are many silver complexing agents that might be used; Pouradier et al. give an extensive list [121]. Thiosulfate is almost always the substance of choice as it is inexpensive and easy to handle. The fixing reaction is:

where n is usually 2 or 3 depending on the conditions and the concentrations of the solution components. The kinetics of reaction are complex, depending on the diffusion of the fixing agent to the silver halide grain, the solution of the silver halide, and the diffusion of the resulting silver complex away from the grain. Examples of fixing reactions being controlled by any one of these steps can be found in Ref. [146].

Washing is required to remove all the processing chemicals remaining in the film after processing that might have a deleterious effect on the stability of the image. It is also used as an intermediate step in some processes to prevent contamination of one bath from a preceding one or from unwanted reaction taking place in the gelatin layer.

1.4 Spectral Sensitization

1.4.1 Introduction

For color photography, a silver halide system must be sensitive to wavelengths throughout the visible region of the spectrum. As detailed below, the intrinsic absorptions of silver halides only occur in the blue and ultraviolet regions. Suitable dyes, called sensitizing dyes, are used to induce longer-wavelength sensitivity. The process, called spectral sensitization [147], was discovered in 1873 by Vogel [148]. Vogel's discovery was serendipitous. He observed that photographic plates to which a dye had been added to reduce scattered light were made sensitive to the wavelengths that the dye absorbed [149]. He and other chemists tried many other dyeing materials, mainly from natural sources, including even bullock's blood! [149]. The chemical technology of spectral sensitization is now highly advanced, and several

aspects are discussed in the following sections. Spectral sensitizers are usually synthetic dye molecules, of which several examples are given below. Much early work was devoted to discussions of the mechanism of the sensitization process, and particularly whether energy or electron transfer was responsible [147]. It is now well accepted that sensitization takes place via electron transfer from the excited state of the sensitizing dye to the silver halide [147, 150], consistently with the Gurney–Mott mechanism for latent image formation [97].

In addition to inducing sensitivity beyond the intrinsic region of the silver halide crystal, the sensitizing dyes are used to separate the sensitivity of the silver halide emulsion into the red, green, and blue regions of the visible spectrum, as required for full color reproduction [151]. An ideal sensitizing dye should be strongly adsorbed to the surface of the silver halide microcrystal, have strong electronic absorptions, and have narrow absorption bands so that the different parts of the spectrum can be selected [152]. Most importantly, the energy properties of the dye's excited states should be such that electron transfer from the excited state of the dye to the conduction band of the silver halide is exothermic.

1.4.2 Electronic Properties of Silver Halides

Silver halide microcrystals used in photographic applications consist of silver bromide, silver chloride, or silver bromide with added silver iodide and/or silver chloride [153]. Intrinsic (band-gap) light absorption of these materials occurs in the blue and near-UV regions of the spectrum [154]. Absorption in this region results in promotion of an electron from the valence band of the semiconductor silver halide, and formation of either a “free” conduction band electron (and a corresponding valence band hole), or a weakly bound exciton, in which the electron and hole are coupled [154]. The band-gap absorption consists of higher-energy allowed “direct” or “vertical” transitions, and lower-energy “indirect” or “nonvertical” transitions, which are observed as a long-wavelength tail. The exact absorption spectra of the crystals depend upon their composition, crystal structure, and preparation method. Representative spectra are shown in Figure 43 [155, 156]. In the language of solid-state physics, the indirect transitions involve a change in wavenumber vector, k , which means that the electronic transition involves a change in the linear momentum of the electron, and are thus partially forbidden [155, 156]. To conserve momentum, such transitions must take place via a mechanism involving vibrations of the crystal lattice, i.e., phonons, and are thus also somewhat temperature-dependent [154]. In the higher-energy region, exciton absorptions may also occur. The extent to which the band-gap and exciton transitions overlap is a function of silver halide composition and crystal structure. The excitons may dissociate into free electrons and holes, and in fact the energies required to do so are rather small, ca. 0.002 eV for AgBr and ca. 0.04 eV for AgCl [157].

Thus, absorption of light with any energy larger than the indirect band-gap energy (3.29 and 2.70 eV for AgCl and AgBr, respectively [158], which correspond to wavelengths of around 410 nm for AgCl and around 490 nm for AgBr) results in the efficient formation of conduction band electrons. As discussed above, it is the

Figure 43. Optical absorption spectra of silver chloride and silver bromide crystals at room temperature. A is the absorption coefficient, which is defined as the fractional decrease in transmitted light intensity due to absorption, per unit thickness [154]. Figure adapted from [154].

accumulation of such conduction band electrons in suitable trap sites that results in the formation of the latent image [159]. Latent image formation occurs with variable quantum efficiency, depending upon the number and nature of the electron trap sites. Modern photographic emulsions are chemically doped to optimize electron trapping [160], and a stable cluster of four silver atoms can be formed with absorption of only a small number of photons, usually around 15–20 [161].

1.4.3 Sensitizing Dyes

The most useful dyes for photographic applications belong to the cyanine class [152, 162]. Typical examples are given in Table 11, together with relevant electrochemical data and excitation energies. The structures consist of two heterocycles joined by a methine chain of variable length (Figure 44).

Historically, the terms simple cyanine, carbocyanine and dicarbocyanine have been used to designate generic cyanine structures containing one, three, and five methine carbons in the chain joining the two heterocycles (Figure 44). Dyes that differ only in the number of methines in the chain are called a vinylogous series. The

absorption maxima for a representative of such a series are given in Figure 45. The maximum shifts by approximately 100 nm to the red per unit increase in the number of vinyl groups.

Adsorption isotherms of cyanine dyes on silver halide crystals are consistent with Langmuir behavior, and indicate a close-packed monolayer of dye on the surface of the silver halide crystal [163]. This is supported by the observation of large shifts in the absorption spectra of the adsorbed dyes compared with the absorption spectra of the dyes in dilute organic solution. An example is shown in Figure 46.

The spectral shifts are assigned to the formation of dye aggregates. Two kinds of aggregates are commonly observed for dye structures such as these, the so-called J- and H-aggregates [152, 164, 165]. The differences between these two are best under-

stood in terms of the simplified pictorial representation given in Figure 47, which shows the influence of dimerization on the absorption spectrum of an idealized molecule with a long-axis polarized electronic transition. Exciton theory predicts that the absorption band of the monomer will be split into two new bands in a corresponding dimer as a result of dipole–dipole interactions [165, 166]. The two transitions correspond to the two possible relative directions for the change in dipole moment in the two molecules upon excitation, as indicated in the Figure. The structures in Figure 47 represent extreme situations. In aggregated dyes, a range of relative orientations between the dyes are possible, defined by the angle between the transition dipole moment and a line joining the molecules, α , as shown in Figure 48. As α tends towards zero, the electronic properties of the aggregate resemble those of the end-to-end dimer of Figure 47, and the lower-energy transition becomes allowed. As α increases towards 90° , the electronic properties resemble

Figure 47. Idealized energy levels and most probable electronic absorptions, E_{abs} , of one monomeric and two dimeric dye structures. The arrows represent the directions of the localized transition dipole moments. The transition in the “face-to-face” aggregate is representative of that in an H-aggregate and the transition in the “end-to-end” structure is representative of that in a J-aggregate.

Figure 48. Some representative arrangements for aggregated dye molecules. A and B have values for α which are less than 45° and are examples of J-aggregates. C, with a value for α of greater than 45° , is an example of an H-aggregate [157].

the face-to-face dimer more, and the higher-energy transition becomes allowed. The J-aggregates are those with small values of α , in which the low-energy transition is observed to be stronger in absorption than the higher-energy transition. The H-aggregates have larger values of α and the higher-energy transition is observed to be stronger of the two. It is the longer-wavelength absorbing J-aggregates which are found to be the most photographically useful. Recent scanning tunneling microscopy (STM) work on J-aggregated cyanine dyes on silver halide crystals has confirmed that the schematic ideas of their structure derived from the theory considerations given above and extrapolations from crystal structures of the dyes are basically correct [167].

The formation of a J-aggregate has a significant influence on the excited-state dynamics of the sensitizing dyes [168–170]. On silver halide crystals, the excitation is found to be very mobile within the aggregate and is found to sample many molecules during the excited-state lifetime [171]. As a consequence of this high mobility, the excited state is extremely sensitive to quenching [158]. As a consequence, the J-aggregate dynamics are found to be sensitive to the details of the surface and the method of adsorption. Experiments have been performed in which the aggregate size was varied by dilution of a sensitizing dye by another geometrically similar dye with a much higher excited-state energy. It was found that the total rates of non-radiative decay increased with increasing aggregate size [172, 173]. This was assumed to be a consequence of the fact that with increasing aggregate size, the excitation is delocalized over a larger area and is thus more susceptible to quenching (see below). There is the possibility of coherent delocalization of the excitation over a number of molecules in the aggregate which is predicted to give rise to an enhanced (superradiant) radiative decay for the aggregate [174, 175]. Although such an effect has been observed in a low-temperature glass [168], no significant superradiance has yet been observed for J-aggregates adsorbed on silver halide [172, 173].

1.4.4 Sensitization Mechanisms

As discussed in Section 1.4.1, the relative importance of electron injection and energy transfer was debated in the earlier literature on spectral sensitization [147]. Support for the former mechanism accumulated, however, from extensive correlations of the effectiveness of sensitization with the electrochemical redox properties of the dyes [147, 157, 176, 177], to the extent that energy transfer mechanisms are no longer considered. The usual electron injection spectral sensitization mechanism for silver halide is illustrated in the schematic energy diagram shown in Figure 49(a). The energy of the lowest unoccupied molecular orbital (LUMO) of the dye (E_{LUMO}) is higher than that of the conduction band (CB) of the silver halide, so that electron transfer from the LUMO to the CB is exothermic. The energy of the highest occupied molecular orbital (HOMO) of the dye (E_{HOMO}) is higher than that of the valence band (VB) of the silver halide. The HOMO–LUMO energy gap is smaller than the VB–CB energy gap, so that light absorption by the dye occurs at lower energy and longer wavelength than that of the silver halide. Thus, light absorption by the dye results in promotion of an electron from the HOMO to the

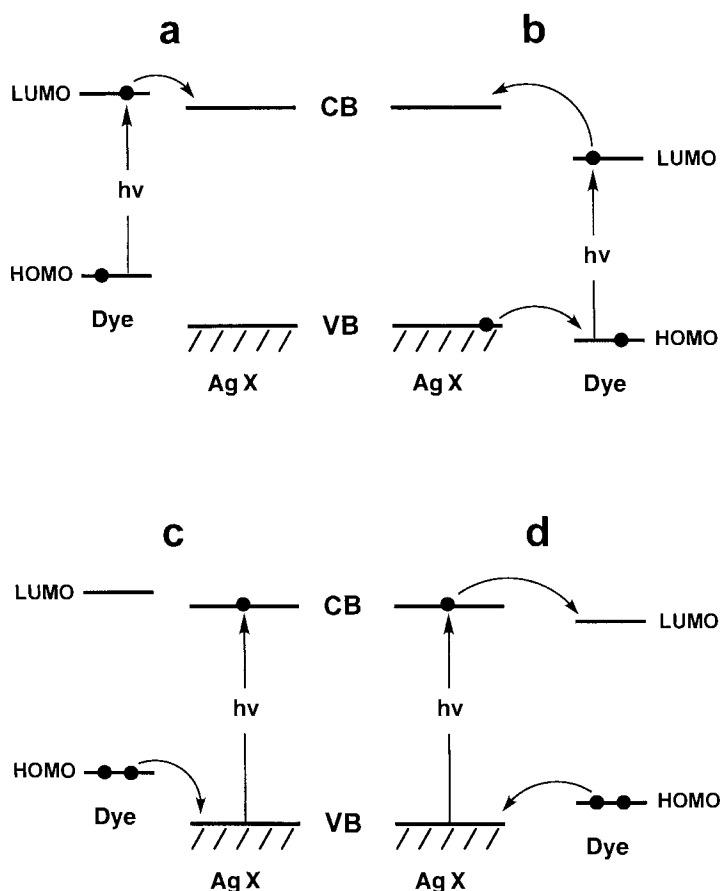

Figure 49. Some possible photoinduced electron transfer processes involving dyes adsorbed to the surface of crystalline silver halide. CB and VB refer to the conduction and valence bands of the silver halide, AgX, and HOMO and LUMO refer to the highest occupied and lowest unoccupied molecular orbitals of the sensitizing dye. a) Electron injection from the excited state of the dye; b) hole injection from the excited state of the dye; c) electron transfer to the valence band after excitation of the silver halide; d) desensitization by an adsorbed dye.

LUMO, which is subsequently injected into the CB of the silver halide. This sensitization mechanism is known as the electron-injection mechanism, for obvious reasons. Another practical mechanism is indicated in Figure 49(b). Here, the energy gap ($E_{\text{LUMO}} - E_{\text{HOMO}}$) is still smaller than the band-gap energy of the silver halide, but in this case E_{HOMO} is slightly lower than the energy of the VB, and E_{LUMO} is thus necessarily lower than the energy of the CB. Excitation of the dye in this case does not result initially in transfer of an electron from the LUMO to the CB, but in electron transfer from the VB to the now singly occupied HOMO. The product is the radical anion of the dye, which can then transfer an electron to the CB of the

silver halide in a slower second step. Note that this second electron transfer is endothermic. However, unlike the excited state of the dye, the radical anion has a comparatively long lifetime which may allow this endothermic reaction to occur. Once the electron is transferred to the CB it is delocalized and susceptible to trapping, and thus the electron transfer from the dye is essentially irreversible. This sensitization mechanism is called hole-transfer sensitization. The products of these two processes are initially different, an oxidized dye in the case of electron injection, and a neutral dye in the case of hole injection. On longer timescales, however, the "holes" in the valence band and/or the dye may be "filled" by electrons from one or more components of the gelatin matrix.

Figures 49(c) and 49(d) show two other important processes which can occur when the silver halide is excited directly in the presence of adsorbed dyes. In these cases an electron is transferred from the VB to the CB upon excitation, and the holes in the VB may be filled by electron transfer from the HOMO of the adsorbed dye. The product of this process in Figure 49(c) is the same as that from the electron-injection dye sensitization in Figure 49(a), i.e., a dye radical cation and a conduction band electron which may be trapped and contribute to latent image formation. Illustrated in Figure 49(d) is the consequence of excitation of silver halide in the presence of a dye in which the energy of the LUMO is lower than that of the CB. In this case, direct excitation of the silver halide results in a conduction band electron which can be transferred to the LUMO of the dye. Subsequent electron transfer of an electron from the HOMO of what would then be a dye radical anion results in effective deactivation of the band-gap excitation, and overall reduced photographic sensitivity of the silver halide toward direct excitation due to the presence of the dye. This process is known as dye desensitization.

A quantitative understanding of these mechanisms clearly relies upon accurate determinations of the energy levels of the CB and VB of the silver halide, and the dye HOMO (E_{HOMO}) and LUMO (E_{LUMO}). These energies are often related to the appropriate ionization potentials (IP) and electron affinities (EA) measured in the gas phase. Measurements of IP and EA for several dyes have also been made in the solid state and on silver halide using UV photoelectron spectroscopy, although satisfactory quantitative relationships with photographic measurements were not easily obtained [178]. Because of difficulties such as these, most workers have resorted to electrochemical measurements of electron-donating and -accepting ability. Studies using phase-selective second-harmonic AC voltammetry have been shown to be particularly useful, since accurate thermodynamically meaningful redox data for many sensitizing dyes have been obtained in this way [177, 179]. In principle, the energies of the CB and VB by ionization potential and electron affinity measurements can be related to electrochemical data such as these [176]. However, difficulties in determining an appropriate vacuum level, among others, mean that useful values for the CB and VB are not available in this way. Indeed, photographic spectral sensitivity experiments are usually used to determine the effective energies of the CB and the VB on the electrochemical scale [176].

As indicated above, phase-selective second-harmonic AC voltammetry has provided accurate and thermodynamically meaningful redox data for a number of dyes. One interesting consequence of obtaining such accurate electrochemical data

is that the relationship between excitation energy and redox parameters could be explored. The difference between the electrochemical oxidation potential (E_{ox}) and reduction potential (E_{red}) should be approximately equal to the singlet electronic excitation energy for the dye, E_{ex} [180] (Eq. (102)). These two quantities differ by a factor, C , which is a

$$E_{\text{ex}} = (E_{\text{ox}} - E_{\text{red}}) + C \quad (102)$$

measure of the difference in the solvation effects for the redox and excitation processes [177]. C also contains a contribution which arises from the fact that the electronic configurations in the initial and final states for the two processes are not the same [181, 182]. These effects should presumably be fairly constant for small differences in molecular structures, i.e., for a particular class of dyes. For example, a plot of E_{ex} versus $(E_{\text{ox}} - E_{\text{red}})$ for a series of carbocyanine dyes is linear with a slope of essentially unity and an intercept of -0.298 eV [177].

The efficiencies of spectral sensitization are usually measured in terms of a relative quantum yield, Φ_{rel} , which is defined in Eq. (103). Φ_{rel} is the ratio of the number of photons which are required to produce a specific developed optical density in a photographic film to the

$$\Phi_{\text{rel}} = (400E_{400}A_{400})/(\lambda E_{\lambda}A_{\lambda}) \quad (103)$$

number required to produce the same optical density for excitation at a wavelength which is absorbed by the sensitizing dye. Often an optical density of ca. 0.6 above the unexposed level is chosen for the optical density determination, and a wavelength of 400 nm is chosen for the direct excitation of the silver halide, since the sensitizing dyes usually do not absorb at that wavelength. Thus, in Eq. (103), E_{400} [erg cm $^{-2}$] is the incident radiant energy at 400 nm and A_{400} is the fraction of this energy which is absorbed by the film. E_{λ} and A_{λ} are the corresponding quantities at the wavelength of excitation of the dye, λ . The absolute efficiency of electron injection from the excited state of the dye, Φ_s , is given by Eq. (104). Here, k_s is the rate constant for injection of the electron by the dye, k_f is the dye's radiative rate constant, and k_{nr} represents the sum of the rate constants for all of the other processes which deactivate the dye when adsorbed to the surface of the silver halide. Φ_s is equal

$$\Phi_s = k_s/(k_s + k_f + k_{\text{nr}}) \quad (104)$$

to Φ_{rel} when the efficiency of latent image formation is the same for the electrons formed by silver halide and dye irradiation. The difference between the two processes is illustrated in Figures 49(a) and 49(c). Φ_s is equal to Φ_{rel} when all of the holes formed by direct excitation are filled by the sensitizing dyes. That this usually occurs has been clearly demonstrated in many cases.

According to Figure 49(a), electron injection occurs from the LUMO of the dye, the energy of which is related to E_{red} as indicated above. Thus Φ_s should be optimum when the energy of the LUMO is at least equal to the energy of the CB, and

probably higher to accommodate any activation energy associated with the electron transfer process. This means that, on an electrochemical scale, E_{red} should be more negative than the energy of the CB on the same scale. When E_{red} is sufficiently more negative than the energy of the CB, the electron injection efficiency is expected to be constant at the optimum value and should not increase with increasingly negative E_{red} . This is because of the continuum of acceptor states in the conduction band of the silver halide. At every energy level of the LUMO of the dye, there is a corresponding acceptor level in the silver halide, and thus the rate of electron injection is expected to be constant. For dyes with increasingly less negative E_{red} , Φ_s should decrease rapidly as the energy of the LUMO becomes lower than the energy of the CB. In addition to reducing Φ_s , dyes with LUMO energies below that of the CB should also cause desensitization, as indicated in Figure 49(d). All of these effects have been observed experimentally (see, for example, Refs. [147, 150, 152, 183–187]), which is taken as strong support for the electron transfer mechanism of spectral sensitization, rather than an energy transfer mechanism.

More recent work has concentrated on quantitative evaluations of the dependence of Φ_s on E_{red} . Two studies in particular have examined the dependence of spectral sensitization efficiency on the redox potentials of the sensitizers using classical Marcus theory (Eqs. (105), (106)) [188].

$$k_s = k_s^0 \exp(\Delta G^\ddagger/kT) \quad (105)$$

$$\Delta G^\ddagger = (\Delta G^0 + \lambda)^2/4\lambda \quad (106)$$

Here, k_s is the rate constant for electron transfer from the dye to the silver halide as defined above, ΔG^\ddagger is the activation free energy for the reaction, λ is the reorganization energy which is a measure of the extent of nuclear reorganization of the dye molecule and the medium associated with the reaction, and k_s^0 is the maximum attainable rate constant. In the classical Marcus theory, k_s^0 is the rate constant for the barrierless reaction ($\Delta G^\ddagger = 0$), which occurs when $-\Delta G^0$ is equal to λ , i.e., when the reaction exothermicity is equal to the reorganization energy. For bimolecular reactions, the rate constant decreases with increasing exothermicity for values of $-\Delta G^0$ greater λ , the so-called Marcus inverted region [188]. This occurs because of an increasing mismatch between the available energy and that required for optimum reaction. For the case of electron transfer to the semiconductor silver halide, however, the almost continuous range of accessible electronic energy levels above the conduction band means that this energy mismatch does not occur. Thus, for sufficiently exothermic reactions, the reaction rate is expected to be close to the maximum attainable rate, and to be independent of ΔG^0 .

Tani et al. measured Φ_{rel} for various cyanine dyes with differing values of E_{red} , ranging from ca. -1.3 V to ca. -1.6 V vs. SCE [187]. Φ_{rel} was equated to Φ_s (Eqs. (103), (104)), and a value of 10^{10} s^{-1} was assumed for $(k_f + k_{\text{nr}})$. The dependence of Φ_{rel} on E_{red} was then calculated using Eqs. (105) and (106) for k_s , with ΔG^0 assumed to be equal to the difference between E_{red} and the potential for thermoneutral electron transfer from the dye to the CB, E_{red}^* (Eq. (107)). E_{red}^* is thus equivalent to the potential

Figure 50. Dependence of Φ_{rel} on sensitizer reduction potential [187]. The solid curve represents the expected dependence based on Marcus theory using a value for λ of 0.05 eV. The energy obtained for the CB of the cubic silver bromide crystals used in this experiment, E_{red}^* , is -1.37 V, vs. SCE. Figure adapted from [187].

$$\Delta G^\circ = -(E_{\text{red}} - E_{\text{red}}^*) \quad (107)$$

of the CB vs. SCE. With these assumptions, E_{red}^* and λ are the variable parameters. The experimental data and the calculated dependence of Φ_{rel} on E_{red} are shown in Figure 50. The values of the parameters used for the calculated fits were -1.37 V for E_{red}^* and 0.05 eV for λ , respectively. Note the independence of Φ_{rel} of E_{red} when the reaction becomes sufficiently exothermic, as expected for electron transfer to the continuum of states in the CB.

A related series of experiments were described by Hailstone in 1984 [189]. A re-interpretation of his experimental data was given by Muentert et al. in 1985 [190] and in 1999 [158], using more accurate redox parameters, and recognizing that his

Figure 51. Plots of apparent activation energies for (left) electron injection and (right) hole injection into cubic AgBrI microcrystals versus reduction and oxidation potentials of the sensitizing dyes, and the expected dependencies for ΔG^\ddagger based on Marcus theory, using 0.42 eV for λ , -0.92 V versus Ag/AgCl for E_{red}^* and 1.41 V versus Ag/AgCl for E_{ox}^* . Figure adapted from [158].

experiments included both electron-injection sensitization (Figure 49a) by some dyes, and hole-injection sensitization (Figure 49b) by others. Values for ΔG^\ddagger were assumed to be equal to the apparent activation energies for the sensitization efficiencies [189]. The data were analyzed using the classical Marcus equation for k_s , and the variable parameters were λ and E_{red}^* for the electron-injecting dyes, and E_{ox}^* for the hole-injecting dyes, where E_{ox}^* is the potential for thermoneutral hole-transfer. E_{ox}^* is thus equivalent to the potential of the VB on the electrochemical scale. The experimental data and the calculated dependencies on E_{red} are shown in Figure 51. The values of the parameters used for the calculated fits were -0.92 V for E_{red}^* , 1.41 V for E_{ox}^* , and 0.42 eV for λ , respectively.

Both experiments clearly provide strong support for the electron transfer mechanism, and valuable data related to the energies of the CB and VB, and also the reorganization energies which characterize the reactions. However, the quantitative agreement between the experiments is not particularly good. The differences in the energies of the CB may be due to a large extent to a difference in the values of E_{red} , by ca. 0.2 V, used in the two experiments, presumably as a consequence of differences in the working electrode used in the electrochemical experiments [158]. The difference in the λ values may be due to the fact that only monomeric dyes were

used in the Hailstone experiment, whereas in the Tani experiment the dyes were aggregated, at least to some extent. The differences may also simply reflect the difficulty in obtaining accurate and quantitative experimental data from photographic experiments [191]. Another complication is that the reorganization energy associated with the medium in the photographic systems is probably not the same as the classical solvent reorganization energy assumed in Marcus theory. In the gelatin matrix the medium almost certainly can not completely reorganize on the timescale of the electron transfer process, because of the rigidity of the protein structure. Under these conditions, the energy differences due to different solvation environments may appear as a distribution in energies for the reaction, and not as a reorganization energy. Exactly this situation has been observed recently for electron transfer reactions in polymer glasses [192]. The overall consequence is a smaller apparent medium reorganization energy and more complex kinetics [192].

1.4.5 Kinetic Measurements of Electron Injection

Direct measurements of k_s can, in principle, be made from time-resolved experiments. The problem with such experiments on photographic systems is their extreme sensitivity to light. Indeed, it is virtually impossible to perform many time-resolved experiments with the photon intensities typically used to take actual photographs. Much higher intensities are usually required, with the consequence that much higher concentrations of transient species are produced than in practical applications, and the systems are susceptible to deterioration due to the irreversible nature of the chemistry. Nevertheless, several experiments have been described from which useful data have been obtained.

Early work showed that low light intensity excitation sources had to be used to avoid excited-state annihilation processes [193, 194]. Using a low-intensity mode-locked laser source and single photon counting, Muentert measured the rates of fluorescence decay, k_d , for some typical monomeric cyanine dyes on silver chloride and silver bromide cubic crystals [195]; k_s was obtained from Eq. (108) for k_d , and assuming that $(k_f + k_{nr})$ could be determined from measurements of dye lifetimes in

$$k_d = k_s + k_f + k_{nr} \quad (108)$$

dilute solutions in gelatin. Estimates for k_s of $(1-3) \times 10^9 \text{ s}^{-1}$ and $(3-8) \times 10^9 \text{ s}^{-1}$ were obtained for dyes absorbed on silver chloride and silver bromide respectively. However, at surface coverages greater than 1 %, energy migration was observed and nonexponential decays were observed, even down to 0.2 % coverage [158]. This was attributed to local environment effects due to surface heterogeneity. However, it should be noted that a contribution to the nonexponential decay may arise as a consequence of the medium not being able to reorganize on the timescale of the reaction, as discussed above.

Spittler and Willig and co-workers measured the temperature dependence of k_s for a cyanine dye adsorbed onto silver bromide octahedral crystals [196]. Non-exponential experimental decays were observed and a curve subtraction technique

was used to estimate exponential rates of reaction. From an Arrhenius-type plot of the data, values for ΔG^\ddagger and k_s^0 of 0.09 eV and $3 \times 10^{11} \text{ s}^{-1}$ were obtained. Work on similar systems by Muentert et al., who performed fluorescence lifetime and photographic response measurements as a function of temperature, gave a similar value for ΔG^\ddagger , but a considerably smaller k_s^0 [197]. It was suggested that differences in data analysis techniques were perhaps responsible for the different k_s^0 values. The significance of k_s^0 is that it is related to the magnitude of the electronic coupling between the excited state of the dye and the states that comprise the CB of the silver halide. In the nonadiabatic limit, k_s^0 is given by Eq. (109), where H is the electronic

$$k_s^0 = (4\pi^2/h)H^2(4\pi\lambda kT)^{-1/2} \quad (109)$$

coupling matrix element and the other symbols have their usual meaning [198]. For the range of k_s^0 values which have been reported, H would be ca. $5\text{--}30 \text{ cm}^{-1}$. This is considerably lower than the magnitude of the coupling found in related work on dye sensitization of other semiconductors such as SnS_2 and TiO_2 , where maximum electron transfer rates in the 10^{13} s^{-1} range have been observed [199–201]. The smaller values on silver halide may reflect the fact that, in the experiments performed so far, the energy of the dye LUMO was toward the bottom of the CB where the density of electronic levels may not be as high. Alternatively, the presence of the gelatin medium and/or adsorbed water on the crystal surface may prevent intimate dye contact with the surface [158].

Other time-resolved experiments have attempted to define the effect of aggregation on the rate of electron injection. Muentert and co-workers combined Φ_s and k_d data to determine k_s as a function of the size of the dye aggregate [202, 203]. The aggregate size was varied by diluting with a geometrically similar dye with a much higher electronic optical transition. In experiments on silver bromide octahedra, and silver bromide and silver chloride cubic crystals, an increase in k_s with aggregate size was observed. This was attributed to the fact that as the excitation becomes more delocalized with increasing aggregate size, the probability increases of “finding” a site on the surface of the crystal where electron injection is particularly facile. It was also found that the rate of radiationless decay, k_{nr} , also increases with increasing aggregate size. This was also attributed to the fact that the excitation will have a higher probability of encountering a trap site with increasing delocalization. Tani et al. also studied the effect of aggregate size on the rates of electron injection for AgBr octahedral crystals [204]. The aggregate size was varied from ca. 6 to ca. 14 molecules by varying the agitation temperature used to prepare the emulsion. In contrast to the results of Muentert et al., the data were interpreted as indicating a decrease in both k_s and k_{nr} with increasing aggregate size. The reasons for the differences in the behavior seen in the two sets of experiments are not clear. Willig, Spitler, and co-workers made measurements of the temperature dependence of the fluorescence lifetime of a J-aggregated dye on AgBr octahedral crystals from room temperature down to 6 K [205]. A weak temperature dependence was observed for the rate of electron injection, which was explained as a consequence of a near-coincidence between the energies of the dye LUMO and the conduction band. An estimate for the electron transfer matrix element of ca. $5\text{--}30 \text{ cm}^{-1}$ was obtained,

which is in the same range as that estimated for monomeric dyes on silver halide, discussed above. Significantly, the reorganization energy for electron transfer was estimated to be considerably smaller for the J-aggregated system, ca. 0.03 eV, compared with a related dye monomer system studied previously, ca. 0.3 eV. This was also the conclusion from experiments in which the temperature dependence of fluorescence lifetimes and photographic sensitivity were measured for dyes N and M [206]. In each case a smaller temperature dependence for the aggregate was observed compared with the corresponding monomer, consistent with a smaller reorganization energy for the former. For N, a value for λ of 0.14 eV was estimated for the aggregate, and ca. 0.46 eV for the monomer. The appropriate redox potentials for the aggregates are generally not known, however, and in their absence, interpretation of such experimental data for aggregates will always be uncertain [206].

1.4.6 Supersensitization

Addition of a second dye to a spectrally sensitized silver halide system, where the second dye does not sensitize in the spectral region of the sensitizer, may lead to either a decreased activity (desensitization), or in some cases an increased sensitivity. This latter effect is called supersensitization, and is of great importance in practical photographic applications [207]. The effect has been observed with molar ratios of sensitizer to supersensitizer as high as $10^4:1$, but usually this is closer to ca. 10:1 [207]. More than one mechanism has been suggested for supersensitization; however, an extensive series of studies has provided considerable evidence for the hole-trapping mechanism shown in Figure 52 [208–211]. The clearest evidence in favor of the hole-transfer mechanism is that supersensitization is only observed when the HOMO of the supersensitizer is higher than that of the dye [210]. In later work it was observed that ESR signals attributed to the radical cation of the supersensitizer were observed upon irradiation of the sensitizer [211]. In Gilman's original proposal, the supersensitizer donates an electron to the excited state of the dye,

Figure 52. Hole-trapping mechanism for supersensitization. The supersensitizer, SS, transfers an electron to the excited state of the dye to form the radical anion of the dye, before electron transfer occurs to the silver halide. The radical anion subsequently injects the electron to the CB [207].

Figure 53. Typical sensitizer/supersensitizer combination.

so that the radical anion of the dye transfers an electron to the silver halide. In this way the supersensitizer prevents recombination both from the LUMO of the dye before transfer and also from the CB of the silver halide after transfer. Alternatively, the supersensitizer could donate an electron to the dye after transfer to the silver halide. It is clearly difficult to distinguish between these two mechanisms. In principle, a supersensitizer can be any molecule which is capable of donating an electron to the excited state of the dye (or its radical cation). However, most of the compounds which have been shown to be effective as supersensitizers are cyanine-type dyes or their analogs. A typical supersensitizer/sensitizer combination is shown in Figure 53. Compounds such as these may co-aggregate with the sensitizers, and thus be physically located close to the excited and oxidized sensitizers.

2 Electrophotography

David S. Weiss, J. Robin Cowdery, and Ralph H. Young

2.1 Introduction

The electrophotographic copying and printing industry is based on the inventions of Chester F. Carlson [1]. The fascinating story of Carlson and the development of xerography has been told in books and biographical articles [2]. Carlson received a BS in Physics from the California Institute of Technology in 1930. Following a brief time as an engineer at the Bell Telephone Laboratories he joined the patent department at the P. R. Mallory Company. There he became a registered patent attorney and obtained a law degree from the New York University. Based on personal experience and intuition he saw the need for a method of making copies of documents that would supplant the labor-intensive, time-consuming, and low-quality methods available at the time. In his makeshift kitchen laboratory Carlson discovered that a thin film of an insulating photoconductor on a metal plate could be tribocharged by rubbing with an appropriate material such as cotton. This surface charge could be dissipated in an image-wise manner by exposure through a mask with light of a wavelength where the material was photoconductive. The earliest photoconductive materials used were sulfur and anthracene coated on a zinc plate. The invisible electrostatic image could then be visualized, or developed, by contacting it with a powder comprising particles having a charge opposite to that of the surface. In the earliest embodiment of his invention, Carlson used lycopodium powder. The first image was “10.-22.-38 Astoria”. The image was then transferred to wax paper and fixed by heating. Carlson later dubbed this process “xerography” from the Greek meaning “dry writing”. In 1939 Carlson filed a patent on the electrophotographic process and sought in vain for a company willing to invest in this technology. US Patent 2297691 was issued on October 6, 1942. Finally, in 1944 the Battelle Development Corp., a subsidiary of the Battelle Memorial Institute in Columbus, Ohio, accepted the project. This activity attracted the attention of Joseph Wilson, president of the Haloid Company in Rochester, New York. Haloid manufactured and sold sensitized photographic paper and wet-chemical based

photocopying machines. Wilson, and his research director John Dessauer, saw a promise in this new technology that all the business analysts of the top corporations in the United States had overlooked and Haloid agreed to provide financial support beginning in 1947, through Battelle, for its development. It took many years to bring the technology to commercial fruition. The first commercial application, the XeroX Copier Model A, appeared in 1949. This machine achieved limited success because it required 14 complex manual operations in the making of a copy. In 1955 the XeroX Copyflo printer was introduced. This machine automatically made prints from microfilm. As the commercial emphasis of Haloid shifted to xerography, the company changed its name to Haloid–Xerox. In 1959 Haloid–Xerox introduced the Xerox 914 fully automatic copying machine and this marked the beginning of a true revolution. In the decade after the introduction of the 914, operating revenues grew from \$33 million to \$1.4 billion and in 1969 Haloid–Xerox became the Xerox Corporation. Today xerography and related technologies represent a multibillion-dollar business with many corporations with thousands of employees vying for business.

A schematic of the electrophotographic printing and copying process is shown in Figure 1. At the “heart” of the process is the photoreceptor element. This is a photoconductive drum or a belt as shown, around which all the other process elements are situated. The photoreceptor acquires a surface charge by means of a charging device involving an air corona or a charged roller. The surface charge is then dissipated in an image-wise manner by a light exposure. In a copier the exposure comes from light reflected from a document. In a printer the exposure comes from a computer-driven laser scanner or light-emitting diode (LED) array. The

Figure 1. An electro-photographic process with web-based photoreceptor. (Reprinted with permission from Ref. [3q].)

wavelength of the exposing light must match the photoreceptor sensitivity. Contacting the photoreceptor surface with charged toner particles develops the electrostatic “latent image”. In a copier the exposure is carried out so that in dark areas, such as letters in textual material, the surface charge is retained. In a printer it is the background which retains the surface charge. In most copiers and some printers the charged areas of the latent image are developed with toner particles having a charge of opposite polarity to that of the photoreceptor. In other printers the discharged areas are developed with toner particles having a charge of the same polarity as the photoreceptor. Toner particles (typically 8–15 μm in diameter) comprise colorant, charge control agents, polymeric binder, and additives such as wax and silica. The toner may be in a dry form or dispersed in an insulating liquid. Dry development systems may contain “carrier” particles. These are usually magnetic materials with a coating to control the triboelectric characteristics when mixed with toner. The toned image is then transferred to the desired receiver, typically paper or transparency media, and the image is rendered stable by a combination of pressure and heat. The photoreceptor is then cleaned with a brush or blade to refresh the surface by removal of residual toner and receiver debris. In many cases, at the end of the cycle the photoreceptor is “erased” by a blanket light exposure to ensure that the surface potential has the desired uniformity with subsequent corona charging. In a high-volume printer or copier the photoreceptor undergoes more than 10^5 imaging cycles before replacement. Its composition and architecture and its interactions with the electrophotographic process subsystems primarily determine the life of the photoreceptor. Each photoreceptor must be optimized for the specific process in which it will function. There are many books and review articles on electrophotographic technologies [3].

Photoreceptors are generally divided into two classes, inorganic (such as amorphous Si, amorphous Se, or other chalcogenide glasses) and organic (dyes, pigments and other organic molecules in polymeric binders). We will focus on organic photoreceptors in our discussions. There are many aspects of the electrophotographic process that involve electron transfer. Surface charging of the toner occurs by tribocharging against polymer surfaces and surface charging of the photoreceptor occurs by exposure to ions (generated in an air corona, for example). The mechanistic aspects of these processes will be only briefly discussed. The bulk of the chapter will be concerned with the processes that occur within a photoreceptor during the creation of the electrostatic latent image. Charge generation is initiated with the absorption of light and charge transport occurs within the photoreceptor driven by the internal electric field. Each of these latter subjects will be discussed in greater detail.

2.2 Electrophotographic Developers

There are primarily two types of developer. Single-component developers, typically used in desktop printers, are made up of toner particles only. Two-component de-

velopers, commonly used in high-throughput devices, comprise a mixture of toner and carrier particles. Toner particles generally comprise pigment suspended in a polymeric matrix. The choice of pigment depends on its hue and dispersibility in the binder polymer [4a]. The choice of an appropriate binder polymer is based on its having desirable characteristics for toner manufacturing as well as providing good adhesion to paper and giving the desired surface finish to the toned image. Charge control agents are also commonly used in toner formulations. These are added to control the polarity and magnitude of charge on the toner particles. The charging capability of the toner depends on the chemical composition and concentration of the charge control agent in the toner composite. The ratio of toner to carrier charging sites controls the overall toner charging capability and is altered by changing the relative surface content of each, either by relative concentrations and/or particle sizes [4a]. Toner particles (8–15 μm in diameter) are generally smaller than carrier particles (30–200 μm in diameter), but in some systems the carrier is of comparable size to the toner [4b]. Increasing print quality standards have led to the use of smaller toner particles.

The carrier in a two-component developer is generally ferromagnetic metal or oxide particles coated with a polymeric toner charge control agent. The carrier is used to transport the toner from the development station to the surface of the photoreceptor by forming a “magnetic brush” around a magnetic development roller, with the toner particles electrostatically held to the carrier particles [4a]. Tribocharging occurs during the mixing of toner with carrier. A major challenge in the formulation of developers is to provide a toner with the desired charge that is stable with time and with changes in ambient conditions such as relative humidity (RH) and temperature.

At present, two models are used to describe toner–carrier tribocharging. One invokes electron transfer in which electrons in the occupied orbitals of the material with the smaller work function (higher chemical potential) move to the vacant orbitals in the material with the larger work function (lower chemical potential) [5]. This model is derived from the contact charging mechanism for metals and semiconductors where the driving force for electron transfer is the difference between work functions of the contacting materials [4a, 6a]. Electron transfer proceeds until the Fermi levels of the toner and carrier surfaces become equal, at which point the transfer of electrons ceases. The ratio of toner mass to toner charge has been mathematically modeled as a linear function of toner mass to carrier mass, with the slope and intercept depending on particle sizes, mass densities, and surface state densities [4b].

Another model that describes the charge transfer process between toner and carrier particles invokes “ion transfer”. In this model the tribocharging process involves the transfer of ionic species, not just electrons [5b, 6]. The transferred ions are derived from charge control additives which are present as either ionomers or molecular salts in the polymer binder. For ion transfer to occur, dissociated and mobile ions must be present on the particle surface. Initially, each surface contains ions of both polarities, but after repeated contacts the two surfaces become equally but oppositely charged [6a]. The polarity and magnitude of charge transfer can be predicted for certain systems, based on the structure and composition of the ionic

components. The ion transfer model differs from the electron transfer model in that it takes into account the chemical nature of the ionic components. The ion transfer process has been modeled mathematically to correlate the equilibrium charge between the two surfaces with the chemical structure of the contact ions [6a].

2.3 Organic Photoreceptor Fabrication and Characterization

Figure 2 schematically shows a microscopic cross-section of a typical “dual-layer” organic photoreceptor. Photoreceptors can be fabricated on either a flexible polymeric belt substrate or a rigid drum, depending on the electrophotographic process requirements for a given copier/printer. There are advantages and disadvantages for either type of support, depending on the details of the electrophotographic process [3].

In the photoreceptor represented in Figure 2, the first layer is the substrate belt or drum. Belt substrates are typically organic polymers such as poly(ethylene terephthalate). Drum substrates are typically aluminum. The next layer is the conductive electrode used to make a connection to electrical ground. For metallic drums the electrode is the metal substrate. For nonconductive substrates the grounding layer can be a thin metal layer such as Al, Ni, or Ti, or any material that forms a continuous layer with sufficient conductivity. Next is a layer or layers designed to promote adhesion to the electrode and/or to act as an electrical blocking layer to prevent unwanted dark charge injection. A smoothing layer is often used on aluminum drum photoreceptors. If insulating, these layers will prevent complete photodischarge of the photoreceptor which may be undesirable, depending on the magnitude of the residual potential and the electrophotographic process. For this reason these layers are made as thin as possible. The photoactive layer(s) of most practical photoreceptors include a charge generation material (CGM) and a charge transport material (CTM) in a polymeric binder. The format can be a monolayer,

Figure 2. A schematic microscopic cross-section of a dual-layer photoreceptor. (Reprinted with permission from Ref. [30].)

dual-layer or multilayer structure. In a dual-layer photoreceptor, the charge generation and transport functions are separated into a relatively thin charge generation layer (CGL), typically 0.5–2.0 μm , and a thick charge transport layer (CTL), typically 10–30 μm . The latter controls the device capacitance and therefore the surface charge density at a given surface potential. All commercial photoreceptors utilize hole-dominated transport. Thus, in the configuration shown in Figure 2, the photoreceptor receives a negative surface charge. If a positive surface charge is desired, either a single-layer photoreceptor or an inverted dual-layer photoreceptor (with the CGL on “top”) can be used. Finally, an overcoat layer may be added for physical protection from abrasion and scratches, as well as protection from the corrosive chemicals generated in an air corona. Other than the electrode, all layers are typically coated consecutively from solution with appropriate coating aids, using solvents and coating conditions such that previously deposited layers are not adversely affected by the subsequent coating procedures.

Charge generation materials generally comprise pigment dispersions in a polymer binder. The materials must be manufacturable at the desired cost and amenable to the milling, dispersion, and coating procedures required in CGL preparation. The resulting CGL must have good absorption of light of the wavelength used in the electrophotographic process and have charge generation efficiency consistent with the sensitivity required for the process. There are many types of charge generation materials. Typical examples are phthalocyanines, diimides of perylene-3,4,9,10-tetracarboxylic acid, squaraines, azo pigments, the charge transfer complex between poly(*N*-vinylcarbazole) and 2,4,7-trinitro-9-fluorenone (TNF), and an aggregate of a pyrylium-type dye with bisphenol-A polycarbonate (Scheme 1). These materials and the current understanding of carrier generation will be discussed later.

Charge transport layers comprise high concentrations (40–50 wt.%) of charge transport materials dissolved in a polymer binder. The CTMs must be manufacturable in large scale and soluble in the binder and solvent of choice, yielding a formulation that coats readily to form a uniform CTL. CTMs must exhibit adequate charge mobility in the polymeric binder of choice. Useful hole transport materials have a low oxidation potential and a stable cation radical. Most useful CTMs utilize oxidation of the lone pair of electrons on a nitrogen atom. Typical examples, with the chemical functionality in parentheses, are: arylamines (N-Ar), hydrazones ($-\text{C}=\text{N}-\text{N}-$), enamines ($-\text{C}=\text{C}-\text{N}-$), oxadiazoles (heterocyclic $-\text{C}=\text{N}-\text{N}=\text{C}-\text{O}-$), oxazoles (heterocyclic $-\text{C}=\text{C}-\text{N}=\text{C}-\text{O}-$), and pyrazolines (heterocyclic $-\text{N}-\text{C}-\text{C}=\text{C}=\text{N}-$) (Scheme 2). To date, there has been far less work done on electron transport materials than on hole transport materials. Useful electron transport materials must have a reduction potential below that of oxygen, a common electron trap, and a stable anion radical (Scheme 3). Electron-withdrawing groups, such as nitro or dicyanomethylene, are often used to lower the reduction potential of a parent compound. However, these substituents also tend to decrease solubility and electron mobility. In addition, electron mobility is generally much lower than hole mobility in doped polymer films.

Overcoat layers are used to protect the photoreceptor surface from scratching and abrasion, and chemical degradation due to corona by-products [7]. Overcoats may be relatively thick polymeric layers (microns) or thin (submicron) refractory

materials. These must be applied without damaging the underlying photoreceptor. The sol-gel process has recently been used in the preparation of silsesquioxane coatings that are excellent for abrasion resistance [7a-c]. Diamond-like carbon and other overcoats have been prepared with plasma-enhanced chemical vapor deposition [7d-f].

desired potential, then recording the decrease in surface potential with time. Photosensitivity is determined by charging to the desired potential in the dark and then determining the decrease in surface potential on exposure to light of the desired wavelength. Exposing with a light source identical to that in the intended electrophotographic process is the most useful, but both continuous and flash exposures

are commonly used for convenience. Charge/expose cycling, over a range of temperature and relative humidity, is used to determine the dark and photoconductive stability of a photoreceptor. This testing is often configured to mirror the electrophotographic process for which the photoreceptor is intended.

Photoreceptors may be characterized by optical microscopy for layer structure and architecture. Surface defects may be characterized by atomic force microscopy. Scratch resistance can be characterized by scratching the photoreceptor surface with a stylus of known dimensions under specified loads. Brittleness measurements are

accomplished on films by pulling a loop through a wedge having a specific size of orifice.

2.4 Corona Charging

In the electrophotographic process, the first step in the making of an electrostatic image is to produce a uniform surface charge density on the thin photoconductive layer in the dark. The surface charge, along with the countercharge on the underlying grounded electrode, produces a high field within the photoconductor that facilitates charge generation and transport. The photoreceptor structure approximates a parallel plate capacitor and the surface potential is determined by the surface charges per unit area and the effective capacitance. In Carlson's original implementation the surface charge was obtained by vigorously rubbing a handkerchief on a sulfur-coated zinc plate. The seminal 1942 US Patent mentions rubbing with a silk or cotton handkerchief or a soft fur brush [1a]. Carlson's 1944 US Patent describes an "electrophotographic apparatus" with a charging system consisting of a brush or a roller with a surface of "plush, fur, wool, woven or knit cotton, silk or rayon fabric, felt, hair, velvet or other suitable charging material" [1b]. A major advance in making the electrophotographic process practical was the development of a method for using the ions produced by electrical breakdown in air. Applying a very high potential (several thousand volts) to a conductive wire in air produces a corona discharge [8]. Ions from the corona drift to the surface of the photoconductor under the influence of the electric field between the wire and the grounded electrode underneath the photoconductor film. Key inventions were described in patents issued to Carlson (1952) [9a] and Walkup (1957) [9b] and aspects of the science and technology of corona charging are discussed by Schaffert [3f] and Williams [3i]. In a "corotron" device the corona wire is partially enclosed in a shield with the opening facing the photoconductor. In a "scorotron" the opening is covered with a wire screen. The screen is held at the surface potential desired and acts to control the flow of ions from the corona to the photoconductor surface. When the surface potential reaches that of the control grid, ion flow from the corona wire to the photoreceptor ceases. A third, commonly used, charging device is a charging roller. In this device a conductive roller at a high potential contacts the photoconductor surface. Air ionization occurs across a narrow air gap near the nips, where the roller makes and breaks contact with the photoreceptor, and ions are deposited on the photoconductor surface. All these methods have their advantages and disadvantages, depending on the details of the process and marketing requirements for the copier or printer. The electron transfer chemistry that occurs in the formation of a corona in air will not be discussed here [8].

Using mass spectroscopy, the chemical composition of air coronas has been determined by Shahin. In a corona produced at a positively charged wire, in the presence of even trace amounts of water, the predominant ions are hydrated proton clusters, $(\text{H}_2\text{O})_n\text{H}^+$ [10a]. At 20 % RH, $n = 6$ predominates and at 1 % $n = 4$ pre-

dominates. At $RH < 1\%$, other hydrated ionic species are observed: $(H_2O)_nO_2^+$, $(H_2O)_nNO^+$, and $(H_2O)_nNO_2^+$. In a negative corona the dominant ion is CO_3^- [10b]. Even at a relative humidity of 20–50 %, hydrated ions $(H_2O)CO_3^-$, $(H_2O)O^-$, and $(H_2O)O_3^-$ make up less than 10 % of the total ion population. At 50 % RH the average ion mobility is $1.7 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ for both positive and negative ions, and their kinetic energy is negligible. Photoconductor charging was suggested to involve either charge exchange or ion adsorption at the surface [10c]. The charging of selenium was described in terms of electron (negative charging) or proton (positive charging) transfer with the appropriate “surface states”, with trapping of the charged species near the free surface.

Subsequent studies of the corona charging and dark decay characteristics of semiconductor materials have taken into account the effects of mobile charges in the photoreceptor. Such charges might arise from interfacial charge injection (at either the free or the electroded surfaces) as well as depletion of charge carriers trapped in the bulk. Bulk charge depletion results from the thermal generation and subsequent drift of mobile carriers with the countercharge being trapped [10d]. These processes are obviously important in the charging of a photoconductor surface and underscore the observation that corona charging is a dynamic process with the production of both trapped and mobile charge, the latter giving rise to dark decay. Charge mobility in semiconductor bands is beyond the scope of this review. However, charge mobility in doped polymer systems will be covered later.

There have been extensive studies on the corona charging and dark discharging mechanisms in semiconductors such as selenium [10e–g], selenium–tellurium [10h], and selenium–arsenic alloys [10i], and amorphous silicon [10j]. The models for charging of organic photoconductors have followed similar lines [10k]. Thus the dark discharge characteristics of a photoreceptor using the photoconductive charge transfer complex of poly(*N*-vinylcarbazole) and 2,4,7-trinitrofluorenone (PVK-TNF) [10l], and *p*-diethylaminobenzaldehyde diphenylhydrazone (DEH) in a polycarbonate binder [10m], are understood in terms of interfacial charge injection and depletion of thermally generated bulk charge. Ing and Neyhart discuss positive corona charging of arsenic triselenide in terms of bulk hole generation and surface hole injection [10i]. The surface contribution was found to decrease with exposure to air or with the application of a thin surface-insulating layer. The authors speculate that the effect of air is to produce either an oxide layer and/or a selenium-rich surface. Similar effects are observed with a-Si and a thin surface layer is necessary to retard the surface injection of holes [11]. Thus, the charging of photoconductor surfaces is believed to involve either corona ion absorption and/or electron exchange from corona ions to “surface states”. The details of this process and chemical nature of the “surface states” remain open questions.

In addition to the ionic species, air coronas produce ozone, various oxides of nitrogen, and light from the emission of excited molecular nitrogen [12a]. Corona discharge treatment of polymer films is common in the coating industry. This treatment results in surface oxidation and increased surface energy, for improved adhesion of subsequently coated layers [12b,c]. Goldman and Sigmond, in a study of aluminum corrosion, found that exposure to a corona gave rise to mixtures of aluminum nitrates, hydroxides, and oxides [12d]. The corrosion was greatest with a

negative corona at high RH. They conclude that the corona environment behaves as a unipolar gaseous electrolyte that reacts with aluminum in a manner akin to aqueous oxidation. Nashimoto has shown that the emission of ozone and NO_x depends on the corona polarity, wire composition, and wire diameter [12e].

It has not been fully appreciated that during corona charging of photoconductors the surface of the material being charged is exposed to reactive chemical species, as well as light, and chemical modification of the exposed surface during charging is very likely. There is little doubt that many of the anomalies observed in mechanistic studies of corona charging are due to surface chemistry. Nevertheless, there are few reports on the chemical changes resulting from such exposures and how they impact the electrical characteristics of importance in electrophotographic applications.

Lichtensteiger and Webb reported that negative corona charging of cadmium sulfide and zinc selenide results in surface oxidation [13a], and ozone exposure of amorphous selenium in electrophotographic copiers and printers has been shown to cause surface oxidation to selenium dioxide [13b]. Styrenic charge transport molecules, doped at high loading into a binder polymer to form the hole transport layer of an organic photoconductor, undergo ozonolysis during corona charging in the electrophotographic process [13c]. The chemical breakdown of the hole transport material renders the charged photoreceptor incapable of undergoing complete photo-discharge. This results in a residual potential that increases as the photoreceptor is cycled in the electrophotographic process. Weiss has shown that tri(*p*-tolyl)amine, a typical low-oxidation-potential charge transport material, undergoes a one-electron oxidation to the radical cation when exposed to the neutral gases produced in an air corona [13d]. Because the arylamine radical cations are the charge carriers in hole-transport-based organic photoconductors, increased dark conductivity is observed. Following the corona gas exposure the concentration of the radical cation of tri(*p*-tolyl)amine decreases and there is concomitant formation of nitrated transport material. This chemistry is explained in terms of the electron transfer mechanism of electrophilic aromatic substitution with a nitrogeous species (NO_x , HNO_3 , etc.) serving as the oxidizing agent. Similar effects were observed when the photoconductors were exposed to the gases over concentrated nitric acid. Although there are few literature reports on the effects of corona-generated oxidizing agents, the patent literature has many examples of the use of antioxidants doped into photoconductors to eliminate such effects.

2.5 Charge Carrier Generation

2.5.1 Background and Methodologies

In the xerographic process the charged photoreceptor is image-wise exposed with a light source having an emission at wavelengths that are absorbed by the charge generating material. As a result of this exposure, charges are generated and drift through the photoreceptor, reducing the internal field and neutralizing the surface

charge. This produces an image-wise pattern of surface charge, and surface potential, on the photoreceptor. In this section we will discuss the electron transfer aspects of the chemistry and physics of charge generation in organic photoreceptors. A subsequent section will cover the process of charge transport.

Photoinduced charge generation in organic crystals has been of interest for many years [14], and in recent work the assembly of controlled architectures holds the promise of many potential applications [15]. Inorganic semiconductors have also been extensively studied for photoconductive characteristics. Amorphous selenium and arsenic triselenide [16], as well as hydrogenated amorphous silicon [17], are all currently used in electrophotographic photoreceptors. Discussion of these materials is beyond the scope of this review and we will concentrate on charge generation mechanisms relevant to organic photoreceptors. Many reviews of organic photoreceptors are available [3f,l,o,q, 18]. In organic photoreceptors the bulk of the material making up the photoconductive element is polymeric binder. The active materials are categorized according to their major function in the photoreceptor device, as charge generation or charge transport. Several classes of charge generation materials have seen use in xerography: charge transfer complexes, molecular aggregates, and organic pigments. Transport materials are generally molecular species of low oxidation potential or reduction potential, depending on whether hole or electron transport will be the dominant mode. Transport materials may be homogeneously dissolved, "molecularly doped" in an inert polymeric matrix, or chemically bonded into a polymer. Transport materials and charge transport in xerographic photoreceptors will be discussed separately. In an organic photoreceptor the chemical materials with charge generation and transport functions may be co-dispersed/dissolved in a single layer or separated into charge generation and charge transport layers. Studies of such elements are difficult because of their heterogeneous nature, and interfacial physical and chemical effects, such as mixing and charge transfer, can make unambiguous experimentation difficult to achieve. This section will be divided into discussions of experimental techniques for probing charge generation, current models of charge generation, and application of experimental techniques and models to an understanding of charge generation in organic photoreceptors for xerographic applications. The latter will be discussed largely according to the type of charge generation material.

The quantity of fundamental interest for the characterization and study of electrophotographic photoreceptors is the quantum efficiency of carrier generation. This is the ratio of the number of carriers collected to the number of photons absorbed. The sensitivity of the quantum efficiency to excitation wavelength and to environmental conditions such as temperature, applied field, and photoreceptor composition has been investigated in the elucidation of charge generation mechanisms. In a typical heterogeneous and multilayer structure the overall quantum efficiency is determined by the quantum yield for carrier generation and the efficiencies of charge separation and subsequent transport. In practice these quantities are difficult to separate. Experimental techniques include measurements of transient photocurrent, photoinduced discharge, fluorescence quenching, photoacoustics, and thermally stimulated current.

The transient photocurrent method requires that the dielectric relaxation time be

longer than the carrier transit time. The sample is sandwiched between two electrodes, a field is applied, and the sample is exposed to a short light pulse. Carriers are generated and some fraction is free to drift under the influence of the field to the appropriate electrode. Either the magnitude or time integral of the current may be used to estimate the generation efficiency. There are several limitations with this method. It requires the deposition of an electrode onto an electrophotographic photoreceptor that may influence the dark and/or photoelectric characteristics, and deep trapping may occur at low fields. A technique utilizing delayed-field collection has been developed for application to low-field measurements. In this technique the exposure is carried out at low field and after a short delay (typically a few milliseconds) a high collection field is applied. Since charge transport occurs at high field, low-field transport limitations are avoided. Difficulties with this technique are the possibility that carriers generated at low field may undergo diffusion and/or recombination, which might change the probability of charge separation when the high field is applied [19].

The most common method for determining quantum efficiencies is with a photoinduced xerographic discharge. In this method the photoreceptor is charged with a corona and the sample is photodischarged with a low-intensity exposure. If the charge produced is small with respect to the surface charge the discharge is "emission-limited" and space charge effects are minimized. In practice either the initial photodischarge rate or the voltage decrease produced with a small exposure is determined. Both measurements can be related to generation efficiency by calculating the change in surface charge density (σ) assuming a parallel-plate capacitor geometry with $\sigma = CV$, where V is the measured surface potential and C is the geometrical capacitance per unit area. For organic materials a dielectric constant of 3 is commonly assumed. Quantum efficiencies determined with this technique are influenced by contributions from recombination and carrier transport limitations. With this measurement one must be careful to avoid chemical changes in the photoreceptor caused by exposure to the corona. Because of the difficulty of accurately determining optical densities in thin multilayer film structures, the "xerographic gain" (G_x), defined as charge pairs produced per incident photon, is often determined. Since xerographic discharge involves both charge transport and generation, these measurements are influenced by transport limitations of one or both carriers. Photoreceptors with xerographic gain action spectra which mirror their absorption spectra are described as "sympatric", and those where they are opposed are "antipatric". The latter behavior is generally an indication of charge trapping, surface, or interfacial effects.

Field-enhanced fluorescence quenching has emerged as a valuable tool in the study of carrier generation. An electrode is applied to the free surface of the photoreceptor and the fluorescence emission from the charge generation material is monitored as a function of the applied field. It is assumed that carrier generation is the only field-dependent photophysical process, so field-induced fluorescence quenching can be directly related to carrier generation. This technique is unaffected by transport limitations but depends on the assumption of a simple partitioning mechanism where carrier generation is the only process influenced by the applied field.

Photoacoustics have been used in a few instances to determine carrier generation efficiencies [20]. In this technique one determines the heat produced in a photoreceptor sample upon exposure. The energy provided by photon absorption is partitioned between processes that give off heat, such as radiationless decay and geminate charge recombination; and those which do not, such as radiative decay, charge generation, and photochemistry. The photoacoustic signal is determined as a function of field applied to the sample. To simplify the analysis, the sample is chosen such that radiative decay and photochemistry may be neglected and the excitation wavelength is positioned near the low-energy absorption edge. Thus, assuming that heat production and charge generation are competing processes, the generation efficiency is determined from the change in the photoacoustic signal as a function of applied field. An advantage of this method is that it is unaffected by charge transport limitations. Disadvantages are experimental complexity and the necessity to assume a simple energy-partitioning mechanism.

Thermally stimulated currents have been used in a few cases to study carrier generation mechanisms in organic photoreceptors [21]. In this method the sample, with a field applied, is cooled to a low temperature and irradiated. The sample is then slowly warmed and the current measured as a function of temperature. Since geminate pair recombination is retarded at low temperatures, the charges are released only upon warming. By this technique charge generation, recombination, and separation can be studied as a function of applied field and temperature. Experimental complexity is the main disadvantage of this method and the results obtained do not directly address room-temperature phenomena.

2.5.2 Models

Photoinduced charge transfer has been the subject of intense research and summaries can be found in texts [18b, 22] and many reviews. Electron transfer in polymer matrices has been reviewed [22b].

The mechanism(s) of charge generation in organic photoreceptors utilized in electrophotographic applications are complex because most photoreceptors comprise a combination of a pigment (or molecular complex) and a host—a polymer medium doped with an electron donor or acceptor—in one or more often two thin layers. The physics of such devices has been extensively studied but only recently has the chemistry been similarly scrutinized. For example, only recently has it been discovered that the chemical structure of the light-absorbing pigment in some photoreceptors that have been studied for decades was not as had been supposed. This will be discussed later. Also, the importance of the chemical makeup of the polymeric binder is still largely unknown. These are complex systems of immense commercial importance and the details of how they function have been the subject of many penetrating investigations. Recent reviews of charge generation in organic photoreceptors are available [3q, 18d,e].

In organic photoreceptors photoinduced charge generation occurs through an excited state to produce a geminate electron–hole pair bound by their coulombic attraction. These separate into free carriers by a combination of diffusion and drift

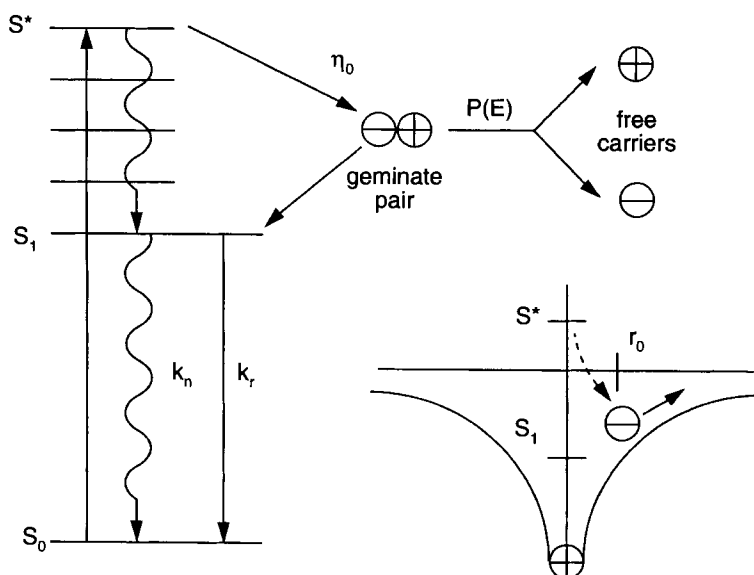

Figure 3. The Onsager model with an insert showing an electron in the coulomb well of a hole. (Reprinted with permission from Ref. [18d].)

in the applied electric field. Free carrier generation is described as “intrinsic” when it involves only one molecular species. When charge generation involves interactions of the excited state with a donor or acceptor it is described as “extrinsic” or “sensitized”. The dependence of the carrier generation efficiency in organic photo-receptors on field, temperature, and excitation wavelength has been described within the framework of models that will be described below.

An extensively used model is based on a 1938 theory from Onsager describing geminate ion pair recombination (Figure 3) [23a]. In this model it is assumed that a hot excited state (S^*) partitions between geminate pair formation and radiationless decay to S_0 . Onsager’s 1938 theory derives from the solution of the diffusion equation for a charge pair under the influence of both their coulombic attraction and an applied field. The model has two parameters, the quantum yield for geminate pair formation, η_0 , and the initial separation distance of the charges, r_0 . The only electric-field-dependent process is assumed to be separation of the geminate pair. In much of the early work a spherically symmetric δ -function was assumed for the distribution of geminate pair separations. Thus the generation efficiency is determined by the probability for geminate pair formation and the subsequent branching ratio of the geminate pair in the field-dependent formation of free carriers versus recombination. With this form of the model it is predicted that at very low fields the generation efficiency becomes a linear function of the applied electric field where the dependence (slope/intercept ratio) is determined solely by the dielectric constant and temperature. Agreement with this prediction is considered to validate the use of the model. Applying this model to systems with charge transfer excited states

resulted in unreasonable initial separation distances of 2–3 nm. The 1938 Onsager theory assumes a boundary condition of total geminate recombination at zero charge pair separation, and Braun has proposed that this assumption is inconsistent with a metastable charge transfer state [23b]. He proposed a more appropriate model based on a 1934 Onsager theory describing the effect of an applied electric field on ion pair dissociation in a weak electrolyte. Recently, Smirnov and Braun proposed the use of a nonspherical distribution for the initial ion pair distribution in charge generation from charge transfer or exciplex states [23c]. This modification of the Onsager model provided intuitively reasonable initial ion pair separation distances. The Onsager-based models predict a photoconductivity threshold at higher energies than the absorption threshold, and wavelength-dependent quantum yields for carrier generation. Fluorescence from S_1 will be field-dependent to the extent that geminate pair recombination to S_1 occurs in competition with field-dependent carrier separation. Applications of this model to charge generation in amorphous materials have been reviewed [23d]. Noolandi has reviewed theories relating to the time dependence of geminate recombination with respect to the Onsager models [23e]. Ries and Bässler have applied Monte Carlo techniques to the study of geminate recombination [19b]. From the simulations it was concluded that recombination within an amorphous solid with a Gaussian energy disorder could be explained by carrier diffusion into trapping sites which are a consequence of the disorder plus traps of unknown origin. For the latter, incipient dimers were suggested.

In many organic photoreceptor systems the absorption and photoconductivity thresholds coincide and the quantum efficiency of free carrier generation is independent of excitation wavelength. The internal conversion model has been proposed for these systems. This model is a special case of a more general theory of geminate recombination from Noolandi and Hong [24]. In this model internal conversion results in S_1 , which produces a geminate charge pair in competition with fluorescence and radiationless decay (Figure 4). This model predicts coincidence of the photoconductivity and absorption thresholds, wavelength-independent quantum yield for carrier generation, and fluorescence quenching with increasing applied electric field.

Sensitized carrier generation occurs when the thermalized excited state (S_1) undergoes electron transfer with an electron donor or acceptor followed by diffusion and field-assisted drift of the free carriers (Figure 5). This mechanism was proposed by Needler to explain the photoconductivity and fluorescence quenching observations in polymers containing dissolved dyes and arylamine donors [25a]. In most organic photoreceptors the excitation occurs within a pigment particle and the singlet exciton diffuses to the surface, where it may undergo electron transfer with either a donor or acceptor which is also typically the charge transport molecule used in the photoreceptor. Characteristics of this mechanism are fluorescence quenching and enhanced carrier generation efficiency in the presence of the small molecule donor or acceptor. The charge transfer mechanism of carrier generation has generally been analyzed in terms similar to solution-photoinduced charge transfer reactions. Key factors are thought to include the extent of charge transfer interaction, the free energy of the electron transfer, and the reorganization energy of the surrounding medium.

Figure 4. The internal conversion model. k_n , k_r and k_E are rate constants for radiationless relaxation, radiative relaxation, and geminate pair production, respectively. (Reprinted with permission from Ref. [18d].)

Figure 5. The sensitized photogeneration model with electron transfer from photoexcited dye to hole transport molecule. (Reprinted with permission from Ref. [18d].)

A triplet exciton annihilation mechanism has been proposed for charge generation in molecularly doped polymers initiated with very fast, high-intensity, excitation [25b,c]. In this mechanism it is proposed that both charge separation, associated with the Onsager model, and the fusion process are very strongly field-dependent. This model has not been invoked in recent years.

The above models describe the events giving rise to free carrier generation in a photoconductor. In the photodischarge of an electrophotographic photoreceptor there are other processes which may reduce the overall quantum efficiency of the photodischarge. One such process is deep trapping of either or both carriers due to impurities, at interfaces, etc. Thus, the determination of charge generation quantum

efficiencies in organic photoreceptors is complicated by carrier transport limitations. Much of the development of commercially viable photoreceptors for electrophotography has involved the technology for ensuring that such trapping does not occur. Xerographic discharge is exquisitely sensitive to the effects of carrier trapping with the telltale signature of an increasing residual potential (incomplete photo-discharge) with cycling. Photoreceptors for high-volume copiers and printers have intended lifetimes of $>10^6$ imaging cycles.

Another charge-depleting process is the recombination of free carriers as they drift in opposite directions through the bulk of the photoreceptor layer(s). Diffusion-controlled bimolecular recombination depends upon the carrier concentrations and has been described by a theory due to Langevin [26a]. The effects of bimolecular (Langevin) recombination on photocurrent and photoinduced discharge have been modeled by Chen [26b], Kerr and Rokos [26c], and Young [26d]. If the observed photodischarge depends on the total exposure and not the exposure duration, the photoreceptor is said to exhibit reciprocity. High-intensity reciprocity failure describes the situation where the photodischarge efficiency is decreased with high-intensity, short-duration exposures due to bimolecular recombination. Such a situation has been described in a single-layer photoreceptor based on a dye-polymer aggregate charge generation material (discussed in more detail later) [26e]. Figure 6 shows the effects of exposure intensity (6 ns laser pulse) in the photodischarge of this photoreceptor with strongly absorbed light with electron-transport-dominated discharge. The emission-limited discharge data were obtained using sequential low-intensity, 6 ns, laser flashes. The high-intensity exposure data were obtained with individual charge-expose photodischarges with different intensities. Similar results

Figure 6. Surface potential vs. exposure characteristics for a single-layer photoreceptor with a dye-polymer aggregate CGM. The exposure (680 nm) is strongly absorbed and the initial surface potential is -500 V. (Reprinted with permission from Ref. [26d].)

were obtained for hole-dominated photodischarge. These results were explained by a combination of Langevin recombination and carrier trapping. Buettner and Mey both predict and demonstrate that high-intensity reciprocity failure does not occur in photoreceptors with a linear field dependence for carrier generation [26f].

2.5.3 Organic Photoreceptors

In an electrophotographic process the sensitivity of the charged photoreceptor to the exposing light is of paramount importance. The exposure must produce a surface potential discharge sufficient for the success of the subsequent development process. As has been discussed, this sensitivity is related to the carrier generation efficiency of the photoreceptor. Although high photosensitivity is generally desired it is more important that the photosensitivity be mated to the exposing light source wavelength and intensity, and that the desired photodischarge characteristics are maintained over thousands or even hundreds of thousands of imaging cycles. Thus, although high-field carrier generation efficiencies of >0.8 are readily achieved using today's technology, this alone does not ensure commercial viability. It is in this mating of materials with technology that successful photoreceptors have been realized.

The simplest possible embodiment of an electrophotographic photoreceptor would be a single layer of a polymer molecularly doped with a charge transport material or a polymer with a transport-active pendant group. In the absence of a specific charge generation material such a device would generally only be sensitive to ultraviolet exposure and would have no practical utility. Nevertheless, many fundamental studies were carried out on such devices and the results obtained are of interest, especially in terms of the changes in mechanism observed with the addition of a charge generation material.

Poly(*N*-vinylcarbazole) and molecularly doped polymers

Poly(*N*-vinylcarbazole) (PVK) is the prototypical photoreceptor hole transport material. It was among the first to be investigated and it still finds application in organic photoreceptors. Many reviews of charge generation in PVK are available [3o,q, 18a, 27a–e]. In 1965 Hoegl reported photoinduced discharge of PVK films [28a]. The xerographic gain was found by Regensburger to closely follow the absorption spectrum (Figure 7) [28b]. The sample comprised a 7.6 μm PVK layer solvent-coated on an aluminum substrate. The illuminated surface was corona-charged positively to 630 V. Also shown on this plot is the fluorescence emission spectrum obtained with 253.7 nm excitation. The two emission bands are believed to be due to two excimers differing slightly in the extent of face-to-face carbazole overlap. As we will see later, these excimers figure prominently in the charge generation mechanism of PVK. The field and wavelength dependencies of the photogeneration efficiency were determined by Borsenberger and Ateya (Figure 8) using the photoinduced discharge method [28c]. In these experiments the PVK was solvent-coated onto a nickelized poly(ethylene terephthalate) (PET) substrate. The

Figure 7. Absorption and fluorescence spectra, and the xerographic gain of poly(*N*-vinylcarbazole). The initial surface potential was 630 V. (Reprinted with permission from Ref. [28b].)

Figure 8. Wavelength dependence of the photogeneration efficiency in poly(*N*-vinylcarbazole). (Reprinted with permission from Ref. [28c].)

exposure was incident on the positively charged surface. Exposure of a negatively charged surface produced no photodischarge, showing that holes are the only mobile species produced in PVK. The quantum efficiency was independent of film thickness and of which surface was irradiated. The field dependence data (345 nm excitation, 23 °C) were fitted to the 1938 Onsager model with $r_0 = 2.6$ nm and $\eta_0 = 0.11$. With increasing temperature r_0 remained constant but η_0 increased to 0.15 at 51 °C. There is substantial deviation of the experimental data from the theory at low applied fields. The authors attribute this to surface recombination or trapping. The observed wavelength dependence is similar to that of Regensburger (Figure 7). In this case the quantum efficiency increased in steps with decreasing wavelength. The transition wavelengths were identified with transitions to higher excited states of PVK. From the field dependencies in each region it was determined that η_0 remained constant but the thermalization distances, r_0 , increased with decreasing wavelength from 2.6 to 2.8 to 3.0 nm. These results were interpreted in terms of ionization occurring from three distinct, vibrationally relaxed, excited states.

More recently Cimrová and Nešpůrek carried out similar investigations of the field dependence of charge generation in PVK films produced by solvent coating on a nickel substrate [28d]. For excitation into the first and third excited states they determined r_0 values of 2.6 and 2.9 nm and η_0 values of 0.17 and 0.14, in reasonable agreement with the Borsenberger and Ateya results. However, the 1938 Onsager model was inadequate at very high electric fields, the temperature dependence of the photogeneration efficiency could not be explained, and the r_0 suggested an unreasonably high charge transfer state energy. Based on their experiments they proposed a new model that was refined in subsequent publications (Figure 9) [28e,f]. The

Figure 9. Schematic of the photophysics and photogeneration mechanism in poly(*N*-vinylcarbazole). (Reprinted with permission from Ref. [28f].)

charge generation mechanism in PVK was studied by emission-limited photo-discharge [28d]. The field and temperature dependencies of the generation efficiency could not be satisfactorily fitted with any of the Onsager models, irrespective of the form chosen to describe the distribution of geminate pair separations. The proposed model incorporated the two excimer states of PVK. In this model the excited carbazole moiety (Cz) in PVK undergoes rapid radiationless conversion to S_1 . S_1 partitions among radiative or nonradiative relaxation to the ground state (k_f and k_n), trapping at either of two excimer sites Cz_g and Cz_t (k_g and k_t), or formation of an electron-hole pair (k_i). Only the higher-energy Cz_g excimer trapping center is presumed to be active for charge carrier generation (k_i). The electron-hole pairs can recombine (k_r) or undergo field-assisted diffusion (k_d) with formation of free carriers.

Since excimer emission predominates in PVK it was assumed that ion pair formation from Cz directly (k_i) could be neglected. Using this kinetic scheme, and the Onsager theory to express k_d , the best data fit was obtained with a Gaussian distribution to describe the geminate pair separation distances. For absorption into S_1 (355 nm) the quantum efficiency for generation was 0.87 and the Gaussian distribution parameter was 0.6 nm. Absorption into S_3 (254 nm) gave a lower efficiency, 0.44, and a larger separation, 0.8 nm. These differences were explained in terms of the penetration depths for the two wavelengths. With 254 nm excitation the light is absorbed near the surface, where with ESCA (electron spectroscopy for chemical analysis) it was determined that the oxygen concentration was approximately double its concentration in the bulk. Oxygen quenching of the excited state was proposed to account for the decreased generation efficiency with 254 nm excitation. Thus, in this model, charge pair formation occurs at excimer sites. The hole (radical cation) is localized at the excimer site and the counterion (electron) at an adjacent carbazole or an acceptor (such as oxygen). Such stabilization could account for the very long lifetimes observed with delayed-field collection [28g].

Many molecularly doped polymers have been studied for photogeneration. Most are single-layer photoreceptors comprising a dopant dissolved in a polymeric binder. The dopant is typically a molecule that will transport holes or electrons. As an example Borsenberger, Contois, and Hoesterey reported on triphenylamine (TPA) dissolved in bisphenol-A polycarbonate (PC) [28h]. The generation quantum efficiency and ion pair separation were determined from the field dependence of generation analyzed according to the Onsager theory of geminate recombination. At a TPA concentration of 45 wt.% the system was described with an η_0 of 0.03 and an r_0 of 2.7 nm. This system was also examined in different polymer binders with 40 wt.% TTA. The field dependence of carrier generation was unchanged but the carrier generation efficiency (η_0) was strongly dependent on the polymer going from 0.027 in PC, to 0.009 in polystyrene, to 0.001 in poly(vinyl butyral) [28i]. Other than this, there have been very few studies of the effects of the polymer binder on carrier generation in molecularly doped polymer systems.

Donor-acceptor charge transfer complexes

It was recognized early in the study of PVK that doping with donors or acceptors dramatically increased the photoconductivity through donor-acceptor charge

transfer complexes [28a, 29a]. The dopant that has received the most attention, and eventually led to the first commercial organic photoreceptor, is 2,4,7-trinitro-9-fluorenone (TNF). Meltz evaluated the field dependence of the quantum efficiency with 550 nm excitation using the 1938 Onsager model and determined an η_0 of ~ 0.23 and r_0 of 2.5 nm for films with a TNF/PVK molar ratio of 0.06 [29b]. At a molar ratio of 1.0, η_0 was unchanged but the ion pair separation distance, r_0 , was increased to 3.5 nm. Hughes determined that bulk carrier recombination in PVK-TNF films was in agreement with the Langevin model for bimolecular recombination [29c,d]. Pfister and Williams studied sensitization by trichloroacetic acid [29e]. A great deal of mechanistic work has been carried out by Yokoyama and Mikawa and co-workers using a variety of electron acceptors [29f,g]. In the PVK/dimethyl terephthalate system, field-induced quenching of exciplex fluorescence was interpreted in terms of a charge generation mechanism involving field-assisted thermal dissociation from a “nonrelaxed” higher excited exciplex state to produce an ion pair with 2.2 nm separation [29h–j]. The ion pair separation increased with increasing electron affinity of the acceptor dopant. Similar fluorescence quenching results were obtained with PVK doped with the electron acceptor 1,2,4,5-tetracyanobenzene and a similar charge generation mechanism was proposed [29k–m]. With these results the authors proposed a general mechanism for extrinsic carrier generation in a donor–acceptor system which involves both exciplex and charge transfer complex states (Figure 10) [29m,n]. The unique mechanistic feature in this scheme is ion pair generation from an excited exciplex state and not from the relaxed exciplex, which fluoresces. The energy diagram for this process is shown in Figure 11. The authors

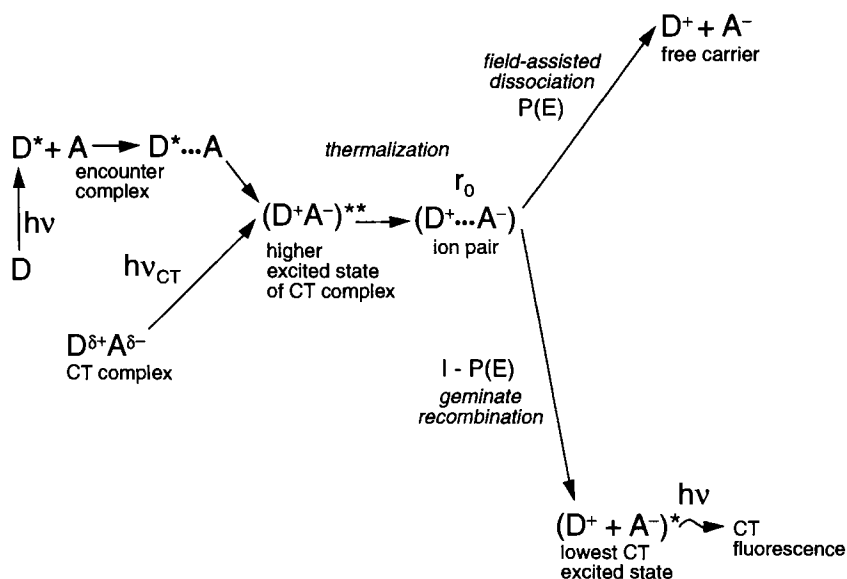

Figure 10. Schematic of a general mechanism for extrinsic carrier generation in a donor–acceptor charge transfer system. (Reprinted with permission from Ref. [29n].)

argue that in the relaxed exciplex, with an ion pair separation of $\sim 0.3\text{--}0.4$ nm, field-assisted thermal dissociation would be energetically unlikely. Furthermore, the measured ion pair separation of ~ 3 nm is consistent with a more loosely bound excited exciplex precursor.

In 1969 IBM commercialized a xerographic photoreceptor using the charge transfer complex formed between poly(*N*-vinylcarbazole) and 2,4,7-trinitrofluorenone (PVK–TNF). This was the first commercialization of an organic photoreceptor for electrophotography. The photoconductor is composed a single layer of a 1:1 molar ratio of PVK–TNF coated from tetrahydrofuran solution onto a metallized flexible support at a thickness of ~ 20 μm [30a]. As a photoreceptor, PVK–TNF has low dark conductivity and adequate photosensitivity to visible light due to the absorption of the charge transfer complex (maximum ~ 500 nm). A unique characteristic of this material is that both holes (carbazole radical cations) and electrons (TNF radical anions) exhibit field-driven charge mobility. Thus, PVK–TNF photoreceptors can be corona-charged either positively (hole-dominated transport) or negatively (electron-dominated transport). Because of the bipolar nature of the

Figure 12. Spectral sensitivity of PVK–TNF (1:1) charge transfer complex. The sensitivity units (per unit area) are coulombs of surface charge dissipated per erg of incident light. The initial surface charge density is 3.5×10^{-8} C. Curve 1 is for negative surface charge (electron-dominated photo-discharge) and Curve 2 is for positive surface charge (hole-dominated photodischarge). (Reprinted with permission from Ref. [30a].)

PVK–TNF photoreceptor there is very little carrier trapping and it can undergo many thousands of charge/discharge cycles with little performance degradation. The spectral sensitivity with positive and negative surface charging is shown in Figure 12. In the IBM 3800 printing system the web-based photoconductor was wrapped around a drum with a supply roll and take-up roll inside. When the photoreceptor became unusable the web was advanced to place fresh photoreceptor around the drum. The photoreceptor was corona-charged to about -750 V and discharged to about -200 V with exposure ($\sim 5.5 \mu\text{J cm}^{-2}$) from a helium–neon laser (632.8 nm) [30b]. Because of potential toxicity questions with TNF this photoreceptor is no longer used.

Donor–acceptor charge transfer complex based photoreceptors continue to be described in the literature and studied using modern spectroscopic techniques but none has been commercialized. For example, the photoconducting charge transfer complex between poly(*N*-epoxypropylcarbazole) and TNF has been studied with transient absorption and time-resolved fluorescence. On the basis of Monte Carlo simulations, the results were interpreted in terms of a heterogeneity of charge transfer complexes with different radiative probabilities and a distribution of initial charge pair separation distances [30c].

Aggregate materials

Developed in 1971 at the Eastman Kodak Company, aggregate photoconductors comprise an aggregate phase of dye–polymer dispersed in an amorphous polymeric matrix [31a]. With the addition of a donor molecule to enhance the photosensitivity and improve the hole mobility, this material was commercialized in both single- and

Figure 13. Absorption spectra of the dye-polymer aggregate CGM. Also shown are the solution spectra of the dye and the nonaggregated dye-polymer film (homogeneous). (Reprinted with permission from Ref. [31b].)

later dual-layer (aggregate generation layer and molecularly doped polymer hole transport layer) architectures. Two-layer aggregate-based photoreceptors are still successfully utilized in copiers and printers manufactured by Heidelberg Digital. The aggregate is a complex between a thiapyrylium dye (4-(4-dimethylaminophenyl)-2,6-diphenylthiapyrylium perchlorate or other suitable anion) (~ 10 wt.%) and bisphenol-A polycarbonate. It forms when a homogeneous film of dye dissolved in the polymer is exposed to dichloromethane vapors [31b]. In the homogeneous film the dye has an absorption maximum at 580 nm. Upon aggregation a dense filamentary fractal-like phase appears and the absorption maximum shifts to 680 nm (Figure 13). Doping with about 40 wt.% of an electron donor such as bis(2-methyl-4-diethylaminophenyl)phenylmethane results in a dramatic increase in the sensitivity as determined from xerographic discharge. Figure 14 shows the aggregate photosensitivity action spectra for the homogeneous film, and the aggregated film with and without donor. In the donor-sensitized aggregate photoreceptor, holes are mobile in the continuous phase and electrons are mobile in the aggregate phase. Electron-transport-dominated photodischarge exhibits a threshold due to high-field trapping in the dead ends of the aggregate filaments and subsequent release of the trapped electrons when the field strength drops [31c]. Figure 15 shows the spectral dependence of the xerographic gain for a single-layer aggregate photoreceptor with

Figure 14. The spectral dependence of the xerographic sensitivity of the nonaggregated homogeneous dye-polymer film, the aggregated film, and the aggregated and sensitized film. The sensitivity is the reciprocal of the energy required for a photodischarge from 500 to 250 V. (Reprinted with permission from Ref. [31].)

positive charging (hole-dominated photodischarge) and negative charging (electron-dominated photodischarge). Analysis of the field dependence of photogeneration for hole-dominated photodischarge with the 1938 Onsager theory gave a primary quantum yield, η_0 , of 0.58 and a thermalization distance, r_0 , of 4.4 nm independent of the exposing wavelength [31d]. Charge generation was explained in terms of a surface-enhanced exciton dissociation mechanism. Thermalized excitons in the aggregate phase diffuse to the homogeneous phase, where exciton dissociation occurs by electron transfer with the donor dopant. Holes are then transported through the continuous phase. Hole photogeneration in dual-layer aggregate photoreceptors follows the same mechanism [31e]. In this case the aggregate charge generation layer containing tri-*p*-tolylamine (TTA) as the sensitizer was in contact with a polyester-based charge transport layer with 40 wt.% TTA as the hole transport material. Since only holes are transported through the transport layer, this photoreceptor was negatively charged in use. From measurements of the field dependence

Figure 15. The spectral dependence of the xerographic gain for positive and negative surface potentials. (Reprinted with permission from Ref. [31c].)

of the photogeneration efficiency with 680 nm exposure, a quantum yield, η_0 , of 0.60 was determined. The thermalization distance, r_0 , depended on the concentration of TTA in the transport layer from 2.0 nm (5 wt.% TTA) to 6.0 nm (40 wt.% TTA). Detailed discussions of charge generation in the aggregate photoreceptor can be found in 1982 reviews by Perlstein [31f] and Perlstein and Borsenberger [31g].

Azo pigments

Azo pigments have been used in electrophotographic photoreceptors for many years. In 1984 McMurtry et al. reported that the IBM 3800 high-speed printer used a two-layer photoreceptor with the bisazo pigment chlorodiane blue (CDB), 3,3'-dichloro-4,4'-biphenylbis(1''-azo-2''-hydroxy-3''-naphthanilide) (Scheme 4), as the charge generation material in a 0.1 μm thick layer and *p*-diethylaminobenzaldehyde diphenylhydrazone (DEH) as the hole transport material in a 16 μm thick layer [32a]. Melz and co-workers (1977) studied the field dependence of the "injection" efficiency determined with the xerographic photodischarge technique [32b]. This is the same as the "xerographic gain" as defined above. The photoinjection efficiency changed by over two orders of magnitude as the CTL was varied from PVK through CTLs composed of an unnamed polymer doped at ~ 50 wt.% with pyrazoline CTMs. The efficiencies decreased with increasing oxidation potential of the CTM. They concluded that for efficient hole injection a CTM with a low ionization potential is required. Kakuta et al. examined photoreceptors with CDB CGLs and CTL comprising polycarbonate or polyester doped at 33 wt.% with a wide variety

Scheme 4. Molecular structures of bisazo pigments demonstrating the three tautomeric forms. (Reprinted with permission from Ref. [33d].)

of hole transport materials [32c]. They found that the energy for half-discharge of the photoreceptor exhibited a linear correlation with the CTM ionization potential. The material with the lowest ionization potential, 2-(*p*-dipropylaminophenyl)-4-(*p*-dimethylaminophenyl)-5-(*o*-chlorophenyl)-1,3-oxazole, had the highest xerographic gain of over 0.2 at the peak sensitivity of 650 nm. Khe and co-workers (1984) prepared and examined a single-layer photoreceptor for positive charging applications [32d]. It was composed of a bisazo pigment, similar to CDB, and a hydrazone hole transport material, in a polyester binder. Charge generation was proposed to occur at the pigment CTM interface. The photoreceptor could be discharged with either hole- or electron-dominated transport (positive or negative surface charge respectively) but the former was more efficient. The xerographic gain reached a maximum of 0.7 at 660 nm and a field of 10^6 V cm^{-1} . Thus the carrier generation efficiency under these conditions is ≥ 0.7 , depending on the various charge loss mechanisms previously discussed.

Perinone bisazo pigments have been studied as generation materials by Murayama and co-workers at Mitsubishi Kasei Corporation for use in dual-layer photoreceptors with CTLs based on hydrazone transport material [33a,b]. The photoreceptors had high sensitivity throughout the visible region and exhibited significantly higher injection efficiencies than a comparable CDB-based photoreceptor. From solid-state ^{13}C -NMR data on bisazo pigment based generation layers, Ono et al. concluded that some pigments were in the hydroxy-azo and some in the keto-hydrazone tautomeric forms [33c]. Their results indicated that hydroxy-azo-based pigments were preferred for increased stability to visible light exposure. Pacansky and Waltman (1992) studied CDB and concluded that the keto-hydrazone tautomer gave greater xerographic gain [33d]. Scheme 4 shows the three tautomeric forms of CDB. From absorption spectra they concluded that CDB is in the azo form in the as-coated

CGL but exposure to tetrahydrofuran, as would happen when it is overcoated with the CTL solution, results in significant conversion to the red-shifted absorption of the hydrazone tautomer. Based on published absorption spectra of CDB-based photoreceptors they propose that the keto-hydrazone tautomer gives the highest xerographic gain. Using a variety of spectroscopic techniques Law et al. proposed that bisazo pigments synthesized using 2-hydroxy-3-naphthanilide derivatives (Naphthol AS and related derivatives) exist as the keto-hydrazone tautomer in the solid state [33e]. They suggest that this is due to a combination of intra- and intermolecular hydrogen bonding. Thus, interpreting quantum efficiency data in photoreceptors with azo-pigment-based CGLs is problematic because the same pigment may actually comprise a different mixture of tautomers, depending on the details of photoreceptor preparation. A great deal of work has gone into the synthesis and examination of various bisazo pigments, in a wide variety of photoreceptor formulations, in the search for those with superior electrophotographic characteristics [33f-j].

Attempts have been made to find relationships between the $E_{0.5}$ xerographic sensitivity (energy for photodischarge to half the original surface potential) and the *p*-phenyl substituents in bisazo pigments prepared from 2-hydroxy-3-naphthanilide. Law and co-workers found that the sensitivity increased up to a point with electron-withdrawing substituents but that very electronegative substituents, such as trifluoromethyl and nitro, actually reduced the sensitivity [33k,l]. Based on X-ray powder diffraction they propose that this effect does not relate to any energetic considerations but is due to the crystallinity, or more specifically the surface area, of the pigment. Pigments with the lowest crystallinity and greatest surface area exhibit the highest sensitivity.

Extensive mechanistic studies have been reported by Umeda and co-workers at Ricoh Co., Ltd. Their work has involved studies of several bisazo and a trisazo pigment (Scheme 5). The latter has commercial interest because of its photosensitivity in the near-infrared. Much of this work has been summarized in recent reviews [34a-c]. Studies on a dual-layer photoreceptor with a fluorenone-based bisazo pigment CGL and a triarylamine CTM-based CTL were interpreted in terms of: 1) absorption in the bulk of the CGL with exciton diffusion to the CGL/CTL interface, 2) competition between exciton deactivation and electron transfer to produce a geminate pair at the interface, and 3) competition between geminate pair recombination and dissociation into free carriers [34d,e]. Figure 16 shows the proposed reaction mechanism. In one study the CGL comprised the pigment Azo-FO-1 dispersed in poly(vinyl butyral) in a 4:10 weight ratio with a thickness of 0.09–0.49 μm . The CTL comprised the CTM APS-1 and a polycarbonate in a 9:10 weight ratio with a thickness of $\sim 22 \mu\text{m}$. Single-layer photoreceptors were prepared which had the same composition as the dual-layer CGL, with thicknesses of 0.15 and 0.27 μm . Luminescence quenching in the dual-layer structure was determined on samples with 0.15 μm CGL and 1.9 μm CTL. Figure 17 is a plot of the xerographic discharge quantum efficiency and photoluminescence intensity as a function of field for the various photoreceptors with excitation at the pigment absorption maximum of 580 nm. The large increase in efficiency from the single- to the dual-layer structure, along with wavelength-independent quenching of pigment lumines-

Scheme 5. Molecular structures and ionization potentials of the bisazo pigments and hole transport materials used in [34b]. (Reprinted with permission from Ref. [34b].)

cence, argues for an extrinsic mechanism [34f]. Thus, the intrinsic mechanism is inefficient because of its large activation energy and geminate pair formation occurs via electron transfer from the CTM to the relaxed pigment exciton. From electro-absorption studies the pigment excited singlet state for Azo-FO-1 was identified as a

Figure 16. Schematic energy diagram for intrinsic photogeneration in an azo pigment and extrinsic photogeneration in the presence of a donor hole transport molecule. (Reprinted with permission from Ref. [34b].)

Figure 17. The electric field dependence of the photogeneration quantum efficiency (580 nm excitation) for photoreceptors with bisazo-based CGMs. Dual-layer photoreceptors (open symbols) with CGL (0.09–0.49 μm) and CTL (22 μm) had a negative surface charge. Single-layer photoreceptors (filled symbols) (0.15 and 0.27 μm) were given negative, and for the thicker sample positive, surface charging. The photoluminescence quenching efficiency (filled diamonds—broken line) was determined on a dual-layer sample CGL (0.15 μm) and CTL (1.9 μm). (Reprinted with permission from Ref. [34c].)

Frenkel exciton. Because the CTL materials penetrate into the CGL during the solvent coating operation, pigment particles are surrounded by CTM and the electron transfer efficiency is not limited by the exciton diffusion length [34f–h]. With the dual-layer photoreceptor, luminescence quenching is independent of field and the xerographic quantum efficiency approaches the luminescence quenching efficiency at high fields [34i]. This is interpreted as electric-field-assisted dissociation of the geminate pair such that at fields $> 3 \times 10^7 \text{ V m}^{-1}$ dissociation is 100 % efficient. At a field of $4 \times 10^7 \text{ V m}^{-1}$ the quantum efficiency is independent of excitation wavelength. Back electron transfer from the geminate pair to re-form the singlet exciton is neglected because of the large energy gap (0.47 eV). In the photoreceptor with a CGL thickness of 0.16 μm and a CTL thickness of 20.3 μm the rate of surface charge neutralization was found to be a linear function of light intensity, indicating that bimolecular recombination is negligible.

The effect of the energy gap on the xerographic quantum efficiency was determined using 26 photoreceptors formulated with three azo pigments and 26 CTMs (Figure 18) [34b,j]. The interfacial electron transfer rates were analyzed in terms of the Marcus theory [34k]. At the high field used in the experiment ($3 \times 10^7 \text{ V m}^{-1}$) the geminate pair dissociation efficiency is unity and is given by the xerographic efficiency. The electron transfer rate constant (k_{et}) was calculated from the xerographic efficiency using the measured photoluminescence lifetime (k_{L}) determined with a single-layer photoreceptor. The electron transfer rate increases with increasing energy gap but does not decrease at very large values as predicted by the Marcus theory. It is clear that the inverted region is not observed in this system. Excited-state polarizabilities of the azo pigments were obtained from electroabsorption studies. Pigment polarizability had no effect on the efficiency of electron transfer but there was an excellent correlation of polarizability with increased probability for geminate pair dissociation into free carriers.

Electroabsorption of Azo-TPA (Scheme 5) is interpreted in terms of a charge transfer exciton rather than a Frenkel exciton as formed by Azo-FO [34l]. From this and other studies it is suggested that carrier generation from charge transfer excitons is more efficient than from Frenkel excitons [34m].

Thermally stimulated currents (TSC) have been used to probe the carrier generation mechanism in a dual-layer photoreceptor with an azo-pigment-based CGL and hydrazone-based CTL. It appears that this technique may be a useful tool in understanding the carrier generation process in organic photoreceptors [21].

In a recent study, exciton diffusion and charge carrier generation were studied in a dual-layer photoreceptor with an azo pigment (4,4'-[(2,5-diphenyl-1,3,4-oxadiazole)-bisazo]bis(3-hydro-2*H*-benzimidazo[2,1-*a*]benz[*d,e*]isoquinolin-7-one))-based CGL and a triarylamine hole transport material (1,3,5-tris[4-(diphenylamino)phenyl]-benzene) in the CTL [34n]. The study utilized steady-state photoconductivity and time-of-flight experiments. The results were interpreted in terms of charge generation via diffusion of strongly bound excitons to the interface region, where the azo pigment and CTM intermix, and electron transfer occurs. This result underscores the importance of CGM/CTM intermixing during the coating process in azo-pigment-based systems where the pigment excited state is a Frenkel exciton.

Phthalocyanine pigments

Discovered in 1927, phthalocyanine (Pc) pigments have been used as colorants in paints and inks for many years. Phthalocyanines have excellent thermal and photostability. The colorant characteristics depend not only on the molecular structure but also on physical factors such as crystal structure, crystal morphology, and particle size and shape. Because of their polymorphism and chemical intractability, their development for use in photoreceptors has taken considerable effort. Nevertheless, this class of pigment is utilized in most commercial copiers and printers that use near-infrared LED or laser exposure sources. Phthalocyanine may be metal-free (H_2Pc), or coordinated with a central metal atom. Metal phthalocyanines which have been studied as generation-layer pigments in photoreceptors include: $AlXPc$, $CoPc$, $CuPc$, $CrXPc$, $FePc$, $GaXPc$, $InXPc$, $MgPc$, $NiPc$, $SnPc$, $TiOPc$, $VOPc$, and $ZnPc$, where X is typically a halogen. Reviews of the xerographic characteristics of these photoreceptors are available [3l,o,q, 18d,e]. However, only metal-free H_2Pc , and more recently $TiOPc$, have been studied extensively with respect to the mechanism of carrier generation.

Phthalocyanines are extremely difficult to purify and characterize because most are only sparingly soluble in common solvents. The typical purification procedure, acid pasting, entails dissolving the pigment in concentrated sulfuric acid followed by precipitation into ice water. It has been found that both the synthetic route and the

purification method have an effect on purity [35a]. In fact, acid pasting may lead to an increase in trace metal impurities in the phthalocyanine. Transition metal impurities were found to introduce energetic states that would be expected to influence both the dark and photoelectrical characteristics [35b]. Train sublimation has been used for phthalocyanine purification. In this technique the material is placed in the hot end of a heated tube which is under vacuum. An inert carrier gas, such as argon or nitrogen, is passed through the tube and the sublimed material condenses in the colder sections of the tube [35c]. Phthalocyanines purified in this manner have altered characteristics when used as generation materials in organic photoreceptors [35d]. A great deal of effort has gone into characterizing the different polymorphs of a particular phthalocyanine and into methodologies for controlling and obtaining the desired polymorph in the charge generation layer of a photoreceptor. Pigment polymorphs have been characterized by electrochemistry, X-ray powder diffraction patterns, optical absorption, and infrared, fluorescence, and ^{13}C -NMR spectroscopy. The various polymorphs of a given phthalocyanine exhibit different photo-generation characteristics and in most cases there is a polymorph with enhanced absorption in the near-infrared which imparts superior characteristics to an electrophotographic photoreceptor. It should be noted that in some cases different groups have used different nomenclature for apparently the same pigment form.

Recently, the chemical structure of some of the polymorphs has come into question. Thus, ClAlPc has been found to form a dihydrate with identical absorption and X-ray powder diffraction characteristics to those that had previously been assigned to a near-infrared absorbing polymorph produced by ball milling [35e]. Also, the X-ray powder diffraction data and infrared spectral analysis of the X-form of H_2Pc have shown it to be the β -form in fact [35f]. In this same work it was suggested that α -MgPc is actually a mixture of O_2 and N_2 complexes. Thus, the chemical structures of the pigments that are formulated into the generation layers of organic photoreceptors are not fully understood. It is clear that the confusion around the chemical structure, polymorph, crystal type, etc., for phthalocyanines used in photoreceptors will be reflected in generation mechanism studies.

Metal-free phthalocyanine (H_2Pc) exists in the α , β , τ , and X polymorphic forms. The α , β , and X forms have been characterized by electrochemistry [36a], fluorescence spectroscopy [36b], and optical absorption [36c]; and α , β , and τ forms by ^{13}C -NMR spectroscopy [36d], optical absorption, and X-ray powder diffraction [36e]. Figure 19 shows the optical absorption spectra of the four forms. The τ form has been further characterized as to particle shape (Types I and II) [36f]. The as-synthesized β - H_2Pc is converted to α - H_2Pc by acid pasting and this can be converted to the X or τ forms with mechanical milling under specific conditions. The X and τ forms convert to the β with thermal, solvent, or extended mechanical treatment.

A dual-layer τ - H_2Pc -based photoreceptor used in Hitachi laser printers has been reported [36e.g]. For optimum photoreceptor performance the milling procedure used to convert α - to τ - H_2Pc had to be tuned to produce needle-like crystals with dimensions of $0.1\ \mu\text{m} \times 1.0\ \mu\text{m}$. The CGL and CTL thickness was 0.5 and 20 μm respectively. The peak sensitivity, $\sim 800\ \text{nm}$, was $5\ \text{erg cm}^{-2}$ for half-discharge from $-600\ \text{V}$ and the photoreceptor exhibited good stability in printing $> 50\,000$ pages. In contrast, another report indicates that extended milling, to convert τ - H_2Pc needle

Figure 19. Absorption spectra of several forms of H_2Pc . Data for α -, β -, and τ - H_2Pc were obtained from [36e] and X - H_2Pc from [36c].

crystals (Type I) to $<0.5 \mu m$ “granular” (Type II) crystals, produced the best photoreceptor [36f]. With CGL and CTL thickness of 0.1 and 20 μm respectively the peak photosensitivity (780 nm) was 2.5 erg cm^{-2} for half-discharge from -600 V . It is also reported that photoreceptors prepared with τ - H_2Pc exhibit higher generation efficiency with increasing dielectric constant of the binder polymers: poly(methyl methacrylate) $>$ silicone $>$ poly(vinyl butyral) $>$ polysulfone $>$ polycarbonate $>$ polystyrene [36h]. The quantum efficiency was also increased in the presence of fine γ -alumina particles. This was ascribed to an increased concentration of oxygen near the pigment surface.

Single crystals of β - H_2Pc were grown from the vapor phase in a tube furnace [36i]. Measured under high vacuum, both holes and electrons had the same mobility ($\sim 1 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$); the quantum efficiency for carrier generation was found to be 10^{-8} at 400 K and had an exponential temperature dependence with an activation energy of 0.21 eV. A mechanism involving phonon-induced exciton ionization was proposed. Pulsed photoconductivity was used to obtain transient action spectra of vacuum-sublimed layers of β - H_2Pc in air [36j]. These were obtained by thermal treatment (320 $^\circ\text{C}$ for 2 h) of the as-deposited layers of α - H_2Pc . An increase in the initial quantum efficiency (2.5×10^{-4}) with time was ascribed to increased absorbed oxygen. Particle dispersions of 5 % β - H_2Pc dispersed in bisphenol-A polycarbonate were studied with delayed-collection photoconductivity, and field-induced fluorescence quenching [36k]. The quantum efficiency was independent of wavelength at low fields; fluorescence quenching was a quadratic function of the applied field. At higher fields there was a linear correlation between carrier generation and fluorescence quenching, indicating 100 % efficiency in geminate pair separation (Figure

Figure 20. Fluorescence quenching and relative photoresponse for β -H₂Pc as a function of applied field with the collection field at $30 \text{ V } \mu\text{m}^{-1}$. (Reprinted with permission from Ref. [36k].)

20). These results were interpreted in terms of the internal conversion model (Figure 4), in which the relaxed singlet state produces a geminate pair (charge transfer state) which dissociates into free carriers under the influence of the applied field. Delayed-collection field experiments indicated that the geminate pair lifetime was tens of milliseconds. In a subsequent study the low-field slope/intercept ratio of the field dependence of the quantum yield approached the Onsager theory prediction only after significant delay times [36l]. This was interpreted in terms of carrier trapping.

X-H₂Pc is prepared by dry ball milling the α -form [36m]. Xerographic quantum efficiencies have been determined in both single- (PVK dispersion) and double-layer (PVK as CTL) architectures as a function of applied field and temperature [36n]. The quantum efficiency saturated at ~ 0.4 (300 K) and increased with temperature. Efficient photoresponse at $>1000 \text{ nm}$ was interpreted in terms of the lowest triplet state as precursor to charge generation. Charge generation studies have been carried out on X-H₂Pc dispersions in a polymer matrix using the photoinduced discharge method [36o], field-induced fluorescence quenching [36p,q], and recombination luminescence [36r]. At low fields fluorescence quenching is a quadratic function of field. At higher fields there is a linear correlation between carrier generation and fluorescence, indicating that at these fields the probability of geminate pair separation into free carriers is unity. The limiting generation efficiency at high fields was ~ 0.8 . The results were interpreted in terms of the internal conversion mechanism for carrier generation, involving dissociation of the first excited singlet state into electron-hole pairs. The effects of doping were determined with fluorescence

quenching studies on X-H₂Pc dispersed in poly(vinyl acetate) [36s]. Metal impurities were doped into H₂Pc at 5000 ppm during acid pasting. The pigment was then purified, converted to the X form, milled with the binder polymer, and coated. Mg, Cd, Mn, Fe, and Pb dopants all produced modest increases in the carrier generation efficiency and all resulted in fluorescence quenching. At higher Fe doping levels the generation efficiency enhancement was less. Generation mechanisms were extended to include doping with electron donors and acceptors, including *N,N'*-diphenyl-*N,N'*-di(*m*-tolyl)-*p*-benzidine (TPD) and 2,4,7-trinitrofluorenone (TNF) [36t]. In all cases there was an increase in the carrier generation efficiency and fluorescence quenching. At approximately monolayer coverage of dopant the generation efficiency in the presence of TNF increased from 27 to 61 %, with the fluorescence quenched 86 %. With TPD the generation efficiency increased to 32 % while the fluorescence was 48 % quenched. There was no evidence for ground-state charge transfer complex formation. These results were interpreted in terms of migration of the singlet exciplex to the pigment surface and charge transfer exciplex formation. The exciplex subsequently relaxes by recombination or undergoes field-assisted dissociation into free carriers. The suggestion is made that perhaps all charge generation in phthalocyanines is extrinsic, involving exciplexes with electron acceptors such as oxygen. Transient photoconductivity studies of metallophthalocyanines are consistent with oxygen charge transfer giving rise to the observed localized-state distribution [36u].

α -, β -, τ -, and X-H₂Pc have been characterized in CGLs, 0.2 μ m dispersed in a polyester, and overcoated with a 10 μ m CTL of 50 wt.% *p*-diethylaminobenzaldehyde diphenylhydrazone (DEH) in polycarbonate [36v]. Quantum yields from the xerographic photodischarge technique depended on the crystal structure, with τ - > X- > β - > α -H₂Pc (Figure 21). The time dependence of the decrease in collected charge with delay in the application of the collection field was also dependent on the crystal form, with α - > X- = τ - > β -H₂Pc. The β -H₂Pc exhibited no decrease in collected charge out to 100 ms (the longest delay investigated). These features were interpreted in terms of the stacking habit of the various forms, with the X and τ forms having a dimer structure.

The effects of interfacial charge trapping were studied in photoreceptors with a vacuum-deposited H₂Pc CGL, or X-H₂Pc dispersed in a polymer binder, overcoated with a CTL of DEH in polyester [36w]. Xerographic charge/expose cycling was used to probe charge trapping. The results indicate that there is significant hole trapping at the CGL/CTL interface and electron trapping in the CTL. Doping the CGL with the electron acceptor and transport material TNF both increases the generation efficiency and reduces CGL electron trapping. The effects of charge trapping at the CGL/CTL interface was studied by comparing the generation efficiencies obtained with photoacoustic and xerographic discharge methods. The photoacoustic generation efficiency is interpreted in terms of geminate and non-geminate recombination in the CGL. The xerographic discharge generation efficiency is interpreted as carrier generation in the CGL, hole injection from the CGL into the CTL, and transport of holes through the CTL [36x]. The injection efficiency at a given field is the ratio of the generation efficiencies determined by the two methods. The photoreceptor was composed of vacuum-deposited H₂Pc overcoated

Figure 21. Photogeneration quantum yield for the various forms of H_2Pc as a function of field. Subscripts indicate single- or dual-layer photoreceptor architectures. (Reprinted with permission from Ref. [36v].)

with DEH in a polyester binder. The injection efficiency was found to be highly field-dependent. The study was extended by varying the DEH concentration in the CTL to show that the injection efficiency was determined by competition between interfacial hole trapping and interfacial transport (Figures 22 and 23) [36y]. Increasing photoacoustic generation efficiency with increasing DEH concentration in the CTL was interpreted in terms of both generation and interfacial hole transport. In addition, photoacoustic generation efficiencies were independent of several transport materials, all of which had mobility of $\sim 7 \times 10^{-7} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$.

Titanyl phthalocyanine (TiOPc) is probably the phthalocyanine most often utilized in commercial electrophotographic photoreceptors. In a study of the wavelength dependence of photoconductivity in single- and dual-layer photoreceptors it was concluded that the pigment was p-type and that generation occurred in the pigment bulk and was unaffected by the presence of a hole-transport molecule electron donor [34n]. The pigment form was not identified in this study.

There are many published reports on photoreceptor fabrication and carrier generation mechanisms using TiOPc. However, this pigment exhibits a wealth of crys-

Figure 22. Photogeneration quantum yield for H_2Pc -based photoreceptors with varying percentages [wt. %] of hydrazone (DEH), as a function of applied field. (Reprinted with permission from Ref. [36y].)

tal morphologies, forms, phases, types, etc., depending on the details of synthesis, purification, treatments, and photoreceptor preparation. Different groups of workers have coined their own terminology to identify the various forms. Thus, Type I and the A form are apparently the same material as are Type IV and the Y form.

Enokida and co-workers report the preparation of several forms: α (acid pasting and acetone treatment), β (wet milling of the as-synthesized pigment in quinoline at 200°C), γ (milling of acid-pasted pigment in *n*-butanol), *m* (acid pasting of the crude pigment in the presence of octachloro- TiOPc), and amorphous (dry ball milling of the crude pigment) [37a]. The forms were characterized by ^{13}C -NMR and X-ray powder diffraction, as well as infrared, ESR, and absorption spectroscopy. The various forms were used in the preparation of dual-layer photoreceptors. Those prepared with the γ form and amorphous TiOPc exhibited high photosensitivity from 600 to 800 nm [37b]. In all cases the photosensitivity increased with decreasing CTM ionization potential.

Researchers from Canon Inc. have reported that the as-synthesized α - TiOPc was converted to the amorphous form by extended ball milling. Stirring in methanol resulted in conversion to a metastable $\text{M-}\alpha$ form [37c]. Milling of the metastable

Figure 23. Photogeneration quantum yield for H_2Pc -based photoreceptors with 33 wt.% hydrazone (DEH) CTM, as a function of applied field. Open-circle data were obtained by xerographic discharge and filled-circle data from photoacoustic measurements. (Reprinted with permission from Ref. [36y].)

form in alcohol solvents gave rise to new M, E, G, and H forms; milling in non-polar solvents produced a novel I form. Photoreceptors with the I form as the CGL pigment exhibited high photosensitivity in the near-infrared. They also reported that acid pasting with sulfuric acid resulted in demetallization to metal-free phthalocyanine and that the use of 1-chloronaphthalene as solvent in the synthesis resulted in $TiOPc$ with some ring chlorination.

Several forms have been described in reports from the Xerox Research Center of Canada. Experiments were designed to find an optimum acid pasting procedure for $TiOPc$ purification [37d]. Acid pasting the as-synthesized pigment using sulfuric acid with precipitation into water gives Type II pigment. However, acid pasting with 20 vol.% trifluoroacetic acid in dichloromethane followed by precipitation into a variety of solvent mixtures produces the following forms: Type I (diethyl ether), Type II (isopropanol), Type III (95:5 methanol/water or 1:1 acetone/water), Type IV (water or 1:1 toluene/water or 1:1 chlorobenzene/water or 1:1 isopropanol/water), Type Z-1 (methanol), Type Z-2 (1:1 ethylene glycol/water), Type X (1:1 methanol/water or 1:1 ethanol/water). Type IV is reconverted to Type I on exposure to dichloromethane. The Type I and V pigments produced high-sensitivity photoreceptors. Type I pigment prepared via different methods had different X-ray

Figure 24. Absorption spectra of Types A, B, and Y TiOPc. (Data obtained from Ref. [37h].)

diffraction, absorption characteristics, and electrophotographic characteristics. Dual-layer photoreceptors were prepared from the various TiOPc forms [37e]. Those with generation layers based on Type I exhibited sensitivity and dark decay characteristics which depended on the method of preparation. The electrophotographic characteristics of the high-sensitivity Type IV were improved by using trifluoroacetic acid in dichloromethane as opposed to sulfuric acid pasting.

Reports from Konica Corp. describe the conversion of amorphous TiOPc (from acid pasting) with solvent treatment [37f]. Treatment with *o*-dichlorobenzene/water (2:1 by weight) produced the Y form, refluxing *o*-dichlorobenzene gave the A form, refluxing tetrahydrofuran gave the B form, and refluxing dimethyl sulfoxide gave the C form. Absorption spectra of the A, B, and Y forms are shown in Figure 24. Calorimetry on the Y form indicated water desorption at 90°C and conversion to the A form at 255°C. These were tested in dual-layer photoreceptors with the CGL composed of 50 wt.% pigment in a mixture of silicone resin and *t*-butyl acetate. The photoreceptor with CGL containing the Y form was the most sensitive. This form had enhanced absorption in the near-infrared that was interpreted in terms of molecular stacking being important for efficient charge generation. The "typical" method of synthesis, using TiCl_4 , resulted in the production of some chlorinated phthalocyanine that had a deleterious effect on carrier generation. TiOPc was found to form adducts with 1,2-diols but these did not exhibit enhanced near-infrared absorption and photoreceptors prepared from them had low sensitivity. Photoreceptors prepared with Y form pigment, synthesized using a chlorine-free synthetic method, exhibited superior photosensitivity and stability over 100,000 printing cycles [37g]. The xerographic action spectra of photoreceptors with CGLs based on the Y and A forms of TiOPc and $\tau\text{-H}_2\text{Pc}$ are compared in Figure 25. The Y form

Figure 25. Spectral sensitivity of Types A and Y TiOPc compared with τ -H₂Pc. The sensitivity is the reciprocal of the energy for photodischarge from -600 to -300 V. (Reprinted with permission from Ref. [37h].)

photoreceptor had peak sensitivity at 850 nm and required 0.75 erg cm^{-2} for a -600 to -300 V photodischarge. This sensitivity corresponds to a xerographic quantum efficiency of 0.9.

Takano and co-workers from NEC Corporation report the preparation and characterization of the Phase I, II, and III forms of TiOPc by solvent treatment [37h]. The pigments were characterized by X-ray powder diffraction and IR spectroscopy, and as dual-layer photoreceptors. Phase III (treatment with tetrahydrofuran) gave the highest-sensitivity photoreceptor.

From studies of xerographic photoreceptor sensitivities it is apparent that carrier generation is influenced by pigment "form". From the chemical and physical characterizations of forms it is clear that differences include crystal structure, pigment morphology, and particle size, as well as adsorbed species such as water or alcohol. Mechanistic studies of charge generation should include a physical and chemical definition of the material under investigation. It has been proposed that differences in photosensitivity among the various forms are related to the molecular overlapping pattern [37i]. Molecular modeling of the Type I and Type IV (near-infrared sensitive) polymorphs indicates that they differ only in a slight rotation of the phthalocyanines about the O-Ti axis and that some of the claimed polymorphic forms are most probably actually due to particle size differences [37j]. The effects of temperature on the absorption spectra of various forms has been interpreted in

terms of intermolecular π - π interactions [37k]. In this study, evaporated films of TiOPc were thermally converted to the Phase I form, then converted to the Phase II form by exposure to acetone vapor or to the Y form by exposure to the vapors of chlorobenzene/water.

The Y form of TiOPc, which has characteristic X-ray diffraction peaks at $2\theta = 9.5^\circ$ and 27.3° , has received considerable mechanistic attention because of its high photosensitivity. The X-ray data correspond to an interplanar separation distance of 93 nm and an interplanar separation along the stacking axis of 33 nm [37g]. Several forms have been independently characterized which have similar X-ray powder patterns and high photosensitivity: the I Form [37c], Type IV [37d,e], Phase 3 [37h], and the γ form [37b]. Water adsorbed on the Y form crystal surface was found to be connected with its high photosensitivity and it was suggested that it was acting as an electron acceptor in carrier generation [37l]. Molecular dynamics calculations were used to model the thermal loss of water with heating in the conversion of the Y to the A form [37m]. Photocurrent and electroabsorption studies of the Y form (and Phase II) indicated charge transfer excitons, whereas only the Frenkel exciton was observed in amorphous TiOPc [37n].

Popovic and co-workers have found a linear correlation between field-induced fluorescence quenching and carrier generation, indicating photogeneration from the first excited singlet state [37o]. In this study the photoreceptor had a dual-layer architecture, having a $0.5\ \mu\text{m}$ CGL (1:1 by weight pigment dispersed in poly(vinyl butyral)) and a CTL of 35 wt.% TPD in bisphenol-A polycarbonate. At 50 % RH the generation efficiency was high and weakly field-dependent (zero-field efficiency of ~ 0.4). The fluorescence intensity decreased and carrier generation efficiency increased with increasing relative humidity but the field dependencies were unchanged. The fluorescence intensity was independent of the presence of TPD or a dry nitrogen atmosphere, ruling out oxygen involvement in carrier generation. These results were interpreted in terms of exciton migration to the pigment surface, where interaction with water leads to carrier generation with concomitant fluorescence quenching. It was suggested that the weak field dependence of generation is due to excitation dissociation in the pigment bulk. Time-resolved fluorescence spectroscopy indicated carrier generation from both relaxed and nonrelaxed intrinsic excited singlet states, but that generation does not occur from trapped excitons [37p]. A carrier precursor state with charge transfer character was suggested from the field dependence of fluorescence quenching. Recently, electric-field-modulated picosecond time-resolved fluorescence spectroscopy has been used to study the carrier generation mechanism [37q]. From the fluorescence decays two singlet excitons were identified. The shorter-lifetime exciton had charge transfer character and was identified as the primary intermediate in carrier generation. Although differing in details, these studies provide a consistent mechanism for carrier generation in Y-TiOPc. The temporal characteristics of fluorescence and charge generation have been studied by nonlinear exciton-exciton annihilation [36r]. This study was carried out in a thin dispersion of Y-TiOPc dispersed in poly(vinyl butyral) binder. Carrier generation was found to occur shortly after creation of the exciton, in an interval (~ 1 ps) which was much shorter than the fluorescence lifetime. Thus, under these conditions of excitation, fluorescence (first excited state) and carrier generation

Figure 26. Quantum yield for charge injection as a function of the redox potential of the hole transport molecule for a TiOPc-based photoreceptor. (Reprinted with permission from Ref. [37t].)

originate from different excited states. It was argued that this result is consistent with many current charge generation models if generation occurs from the non-relaxed lowest excited state or before exciton trapping occurs.

In a study of photoconductivity in single- and dual-layer photoreceptors, with a CGL based on an undefined form of TiOPc pigment, it was concluded that the pigment was p-type and that generation occurred in the pigment bulk and was unaffected by the presence of a hole-transport molecule electron donor [34n].

The influence of CTM oxidation potential on charge injection efficiencies in dual-layer xerographic photoreceptors with TiOPc-based CGL has been investigated [37s]. In interpreting the data it was assumed that the injection efficiency is dominated by electron transfer from the generation site on the pigment particle into the CTM. The data (Figure 26) exhibit a "Marcus inverted region" such that the efficiency decreases with CTMs of very low oxidation potential. A CGM/CTM energy difference of 0.3 V was found to be optimum for electron transfer and the solvent reorganization energy λ was found to be 0.14 or 0.25 eV, depending on the assumptions made for the oxidation potential of TiOPc.

Hydroxygallium phthalocyanine (HOGaPc) has only recently been exploited as a charge generation material. This pigment exists in several forms and structural modifications that are interconverted with various thermal and milling treatments [38a]. Thus, acid pasting produces Phase I that is converted to the high-sensitivity near-infrared absorbing Phase V (absorption maximum 849 nm) by milling with dimethylformamide [38b,c]. Humidity had no effect on the photodischarge charac-

teristics of photoreceptors prepared with the Phase V pigment. Milling with xylene produces the XI form of HOGaPc (absorption maximum ~ 900 nm) and milling with methanol produces CH_3OGaPc . All of these are converted to $(\text{GaPc})_2\text{O}$ with heat (400°C). Electroabsorption studies show that the absorptions have charge transfer character. Crystal structure analysis using the Rietveld technique showed that HOGaPc Phases V and XI involve stacked dimers with staggered overlap. Furthermore, the xerographic gain increased linearly with the magnitude of the electromodulation, indicating that the charge transfer character of the excited state is related to the generation efficiency [38d]. Photogeneration in Phase V HOGaPc has been studied with delayed-collection photoconductivity and fluorescence quenching [38e]. Dual-layer devices were studied. The CGL comprised $0.4\ \mu\text{m}$ of 40 % pigment in poly(vinyl butyral). The CTL was $10\ \mu\text{m}$ of 40 wt.% TPD hole transport material in polycarbonate. At high fields the geminate pair dissociation probability is unity so from fluorescence quenching the zero-field quantum efficiency for geminate pair formation is 0.64, independent of RH. The linear correlation between fluorescence quenching and generation efficiency implicates photogeneration by dissociation of the first excited singlet state. The effects of pigment preparation, the acid pasting process in particular, on xerographic performance has been reported [38f].

Vanadyl phthalocyanine (VOPc) has three crystal forms. Phase I has the major absorption at 725 nm and Phase II at 840 nm [39a]. Figure 27 shows the absorption spectra of Phases II, V, and XI. A dual-layer xerographic photoreceptor with VOPc as the charge generation material had a high-field photogeneration efficiency of ~ 0.2 from 400 to 900 nm [39b]. The effects of molecular structure on aggregation have been studied with *t*-butyl-substituted VOPcs [39c]. Such substitution increases

Figure 27. Absorption spectra of Phase II VOPc (data from [39a]) and Phase V and Phase XI HOGaPc (data obtained from [38b].)

solubility, permitting the use of standard purification techniques. However, the steric bulk prevents formation of the near-infrared absorbing Phase II form. These materials were studied with xerographic discharge [39d]. The Phase II crystalline phase is >300 times more sensitive than Phase I.

Squaraine (squarylium) pigments

In 1982 Wingard at IBM reported a dual-layer photoreceptor using a CGL based on a squaraine pigment (2,4-bis(4-dimethylamino-2-methylphenyl)cyclobutenediylum-1,3-diolate) for use in a printer having a GaAs laser (830 nm) exposing system [40a]. The CTM was the pyrazoline, 5-(*p*-diethylaminophenyl)-1-phenyl-3-(*p*-diethylaminostyryl)-2-pyrazoline (DEASP). This photoreceptor had high photosensitivity from 500 to 900 nm. With a -850 V initial surface potential an exposure of 5 erg cm^{-2} at 830 nm produced a photodischarge to -150 V within 0.25 s. Melz and co-workers had previously reported on photoinjection efficiencies with pyrazoline-based CTLs as a function of applied field [32b]. The initial photodischarge rate was the method used in this study. The pyrazoline CTM with the lowest ionization potential (DEASP) exhibited the weakest field dependence and highest efficiency. At a field of $4 \times 10^5 \text{ V cm}^{-1}$ and 550 nm exposure the injection efficiency of this photoreceptor was 0.4. Another report described, in great detail, a similar squaraine-based dual-layer photoreceptor for use in an IBM printer [40b]. Xerographic characteristics of squaraine-based photoreceptors have been surveyed [40c–e]. Law and co-workers at Xerox have published several accounts of the effects of various squaraine features on xerographic performance. Included are a new squaraine synthesis method for reduced impurities and smaller particle size [40f], CGM binder effects [40g], and squaraine molecular structure [40h]. Law reports that a novel unsymmetrical fluorinated squaraine (3,4-dimethoxyphenyl-2'-fluoro-4'-(dimethylamino)phenylsquaraine) was used to fabricate a photoreceptor with high sensitivity from the visible to the near-infrared [40i]. The CGL comprised squaraine (80 wt.%) in poly(vinyl formal) binder ($\sim 0.4 \mu\text{m}$) and the CTL a solution of 40 wt.% TPD in bisphenol-A polycarbonate ($\sim 26 \mu\text{m}$). The $E_{1/2}$ photodischarge exposure from ~ 1000 V at the peak sensitivity (790 nm) was 1.9 erg cm^{-2} .

Like other pigment generation materials, squaraines that form crystalline aggregates have high photosensitivity. Aggregation results in a broadening of the absorption spectrum into the near-infrared [39d]. Furthermore, in the fabrication of CGLs with bis(4-dimethylaminophenyl)squaraine using poly(vinyl butyral) binder there was a pronounced solvent effect on the xerographic characteristics [40j]. Fluorescence spectroscopy was used to infer that these effects were due to complex formation between the pigment surface and the hydroxyl moieties in the binder polymer. Using a series of squaraines with differing oxidation potentials, it was found that efficient hole injection into the hole-transport material (TPD) occurred when the electron transfer was exergonic [40k]. On the basis of a photoelectrochemical study of a squaraine monolayer, Law and co-workers proposed that carrier generation in squaraine photoreceptors involves electron transfer from excited squaraine to O_2 followed by interfacial electron transfer from the charge transport material to the holes in the squaraine [40l]. Tam used an optoacoustic method to

study photogeneration in a dual-layered photoreceptor with a squaraine-based CGL [20]. At 799 nm ($2.5 \times 10^5 \text{ V cm}^{-1}$) the generation efficiency is 0.039.

Perylene pigments

Perylene-3,4,9,10-tetracarboxylic diimides and related materials have been utilized as charge generation materials in organic photoreceptors for many years. In 1978 Schlosser reported on a dual-layer photoreceptor using the *N,N'*-di(3,5-dimethylphenyl) derivative as CGM [41a]. Using the xerographic technique the limiting quantum efficiency was determined to be ~ 0.3 . This was the same in the presence or absence of a hole-transport electron donor material. The photosensitivity of this photoreceptor decreases rapidly beyond 600 nm, limiting its commercial utility. A single-layer photoreceptor using the same perylene has been studied [41b]. When it was charged positively the quantum efficiency was found to be enhanced by the presence of an electron acceptor (2,5-dichloro-*p*-benzoquinone) and it was suggested that this might be due to electron trapping with a reduction in recombination losses. Increased photosensitivity in the near-infrared has been a major goal of research on perylenes as generation materials in xerographic photoreceptors [41c]. Loutfy and co-workers evaluated several photoreceptors prepared using vacuum-deposited perylene pigments (0.1 μm) as CGMs overcoated with 35 wt.% TPD in bisphenol-A polycarbonate as CTL (15 μm) [41d]. A photoreceptor with bisbenzimidazole substitution had particularly good electrophotographic characteristics with high photosensitivity at 500–700 nm. Calculations and molecular modeling have been extensively utilized in an effort to understand the factors responsible for the molecular overlap leading to enhanced absorption in the near-infrared [41e–g]. These principles have then been applied to the synthesis of new perylene pigments [41h,i]. Popovic has studied the generation mechanism using the delayed-collection field and field-induced fluorescence quenching techniques on electroded samples of pigment dispersed in bisphenol-A polycarbonate [41j]. The quantum yield for carrier generation with a bisbenzimidazole perylene pigment was determined to be 0.36 (100 $\text{V } \mu\text{m}^{-1}$ applied field). A follow-up study was carried out on a dual-layer photoreceptor with a TPD-based CTL. In the presence of TPD the pigment fluorescence was quenched and the carrier generation efficiency was substantially increased, exceeding 0.6 at fields above $\sim 40 \text{ V } \mu\text{m}^{-1}$. This was interpreted as strong evidence for surface sensitization of carrier generation. The field dependencies of carrier generation with and without TPD are very different as well. The charge generation mechanism was suggested to involve exciton diffusion to the pigment/CTL interface where a hole was transferred to surface-adsorbed TPD. An exciton diffusion length of 0.27 μm was determined from the front and rear exposure action spectra [41k]. Another perylene bisimide, the *N,N*-bis(2-phenethyl) derivative, has found utility as a carrier generation material [41l]. Vacuum deposition onto a cooled substrate produces amorphous material whereas deposition at room temperature or above provides polycrystalline material. The latter has enhanced absorption in the red, and higher photogeneration efficiency. Only electrons are transported in the vacuum-deposited pigment layer. The field dependencies of photogeneration, determined by the xerographic method, were analyzed according to

the Onsager formalism to give primary quantum yields of 0.4 (amorphous) and 0.9 (polycrystalline) and thermalization distances of ~ 3 nm for both. Sensitization with tri-*p*-tolylamine (TTA) has recently been reported [41m]. Pigment was vacuum-deposited onto substrates of bisphenol-A polycarbonate doped with TTA. The samples were then exposed to dichloromethane vapors to convert the pigment to the active form and to allow diffusion and intermixing at the CGL/CTL interface. At high fields fluorescence quenching correlated linearly with carrier generation. However, the results indicated a significant component of carrier generation not associated with TTA sensitization but originating from direct dissociation of the fluorescent first excited singlet state into free carriers.

Mixed pigments

Photoreceptors with mixed pigment CGLs have enhanced photogeneration efficiencies as measured by the xerographic technique [42a]. Single- and dual-layer photoreceptors prepared with mixed perylene/metal-free phthalocyanine pigments exhibited enhanced photogeneration efficiencies. Thus, a dual-layer photoreceptor with the mixed pigment (5 wt.% perylene/0.4 wt.% phthalocyanine in poly(vinyl butyral)) exhibited approximately a four-fold increase in generation efficiency at 750 nm over a photoreceptor where the CGL contained only the phthalocyanine at the same concentration. It was found that the perylene, an n-type pigment, had negative surface charge when ball-milled in tetrahydrofuran whereas the phthalocyanine, a p-type pigment, had a positive charge under the same conditions. When mixed in the milling process, the pigments agglomerated and it was suggested that this produces micro p-n heterojunctions that act as sites for efficient carrier generation. Hiramoto and co-workers studied carrier generation in a perylene pigment, 3,4,9,10-perylenetetracarboxylic-3,4:9,10-bis(methylimide), mixed with a small amount of metal-free phthalocyanine [42b]. The mixed pigments were ball-milled in tetrahydrofuran and then dispersed in a polycarbonate binder polymer dissolved in dichloromethane. The addition of 1 wt.% phthalocyanine resulted in >50 % quenching of the perylene fluorescence. This is believed due to either formation of a nonradiative exciplex or energy transfer to the phthalocyanine. At 5 wt.% phthalocyanine, and a field of 10^8 V m $^{-1}$, the generation yield doubled. The fluorescence of both pigments was strongly quenched with increasing applied field. However, for the mixed system the fluorescence quenching decreased with applied field. This unexpected result was interpreted by assuming a dual-path mechanism for carrier generation. Thus a new charge transfer state, with field-independent carrier generation, is formed at the perylene/phthalocyanine interface. This extrinsic mechanism competes with the intrinsic generation from perylene charge transfer states.

2.5.4 Summary of Carrier Generation Mechanisms

From this brief review one can appreciate the complexity of the task of unraveling the mechanism of carrier generation in organic photoreceptors used in electrophotography and the large number of experimental techniques which have been utilized. In most cases the carrier generation mechanism is adequately explained by

variants of the Onsager model, the “internal conversion model” or the “sensitized model” as described. In all pigment systems there appears to be a preferred crystal “form” or “Phase” which has enhanced absorption in the red or near-infrared and in which carrier generation is most efficient. In the simplest cases, a single layer of a pure material, intrinsic generation appears to involve excited states with charge transfer character. Thus, it seems that the excited-state interactions which lead to new low-energy states, and enhanced red absorption, are those which are involved in carrier generation. The presence of donors or acceptors with appropriate energy levels brings in extrinsic, or sensitized, carrier generation. Finally, there is some evidence that in mixed pigment systems an interfacial interaction can enhance carrier generation. Recent studies have probed the energetics of the electron transfer as it effects the rate in the context of Marcus theory. Rates are found to increase to a limiting value with increasing energy gap with no evidence for a so-called “inverted region”. Since many of the photoreceptors studied have multiple components, are heterogeneous, and are contained in an amorphous polymer binder, it is no wonder that the mechanisms are complex and difficult to unravel. Nevertheless, great progress has been made in our understanding of the photogeneration of charges. One measure of this success can be seen in the many commercial applications of organic photoreceptors in electrophotographic copiers and printers.

2.6 Charge Transport

2.6.1 Typical Materials

In an organic photoreceptor photodischarge occurs with the field-driven transport of generated charge through the bulk of the structure. Photodischarge is typically dominated by the transport of one sign of charge even when the charge generation and transport materials are combined in a single-layer architecture. Studies of the mechanisms of charge transport are typically carried out on devices that are designed so that the majority of charge transport occurs in a charge transport layer (CTL). The materials in a CTL must satisfy many requirements.

- 1) Except where charge is injected from the charge-generation layer, the CTL must be very good insulator, so that unexposed areas do not discharge substantially. A 1 cm^2 area of a typical CTL must have a resistance of ca. $10^{12} \Omega$ or more, corresponding to a bulk resistivity of ca. $10^{15} \Omega^{-1} \text{ cm}^{-1}$. Conductivity along the surface of the CTL, which tends to blur an image, must also be very low.
- 2) Nevertheless, where charge is injected from the charge generation layer (CGL), it must be transported rapidly enough for the discharge to be substantially complete before the development step begins (typically a fraction of a second after exposure and charge generation).
- 3) “Deep” charge trapping must be negligible. A gradual accumulation of trapped charge can cause the electrical properties of the photoreceptor to change with

repeated cycling. A rapid accumulation can cause “ghosts” of previous images to be superimposed on subsequent images.

- 4) Injection of charge from the CGL into the CTL must also be rapid and not subject to significant trapping.
- 5) The CTL must be transparent to the image-forming light.
- 6) The CTL must be mechanically rugged, to withstand abrasion by the developer. In machines using a photoreceptor belt (rather than a drum), the entire photoreceptor must also be flexible enough to withstand frequent bending without developing cracks.
- 7) These properties must be stable for long periods at elevated operating temperatures (typically $\sim 40^\circ\text{C}$ inside a high-speed copier). They must not be impaired by reactive species produced in the corona discharge (see above), by contamination from the developer, or by accidental exposure to room light.
- 8) In the course of coating the CTL over the CGL, some intermixing is inevitable. Such “contamination” of the CGL is often important to making the CGL efficient (see above), and in any case it must not impair the performance of the CGL.

Most commercial CTL materials are “molecularly doped polymers” (MDP). In this context, an MDP is a homogeneous solid solution of an electrically active compound (“dopant”, or “charge transport material”, CTM) in a polymeric host. The solution need not be thermodynamically stable, as long as it does not phase-segregate during the anticipated lifetime of the photoreceptor. Typical CTMs are shown in Schemes 2 and 3. The CTM is an easily oxidized electron donor (for a CTL that transports positive charge) or easily reduced electron acceptor (for a CTL that transports negative charge). The polymer is typically a polycarbonate or polyester. It supplies the necessary mechanical properties (toughness, etc.) as well as being an electrical insulator. It does not participate in transport per se, although it can dramatically influence the transport properties of a CTM dissolved in it. For practical purposes, the mechanical properties are paramount, and the transport properties are optimized by using high concentrations of CTM (as high as 1:1 CTM/polymer by weight). The CTM may also act as a plasticizer for the polymer, making it more pliable but also reducing the glass transition temperature. The polymer must satisfy the mechanical requirements described above when it is in a highly plasticized state. CTMs which impart abrasion resistance by virtue of CTL antiplasticization have been reported [43].

Most, if not all, commercial photoreceptors are based the transport of positive charge. The CTM is an electron donor, the charge carrier is a “hole” resulting from donation of an electron from the highest occupied molecular orbital (HOMO), and the charge transport process is formally a self-exchange reaction (Eq. (1)),

repeated thousands of times. The donors are usually triarylamines, tetraarylbendines, or mixed arylamine/hydrazone compounds (Scheme 2). These, and almost all CTMs, feature nitrogen atoms with (formal) lone pairs. Their oxidation potentials

(E_{ox}) are low (cathodic), typically between 0.6 and 1.0 V vs. SCE in acetonitrile or dichloromethane [44].

At least in some cases, a low E_{ox} facilitates the generation and/or injection of a positive charge carrier from the CGL (see above). A low E_{ox} also makes it unlikely that an impurity might have a much lower value and act as a trap for holes [44h]. For obvious reasons, the cation radicals of these compounds must be stable in the CTL environment, and some of the better donors indeed form remarkably stable radical-ion salts, even in fluid solution [44a]. The CTM must be highly soluble in the polymeric host and the solvent used to fabricate the CTM. It must provide a high concentration of electrically active moieties without plasticizing the host polymer excessively. Compounds that meet these requirements are typically rather large and flexible, and they may contain more than one electrically independent moiety per molecule, e.g., 1,1-bis(di-4-tolylaminophenyl)cyclohexane (TAPC) in Scheme 2.

For some applications, a photoreceptor that transports negative charge would be preferable. In fact, the first commercial organic photoreceptor, poly(*N*-vinylcarbazole) doped with 2,4,7-trinitrofluorenone, PVK-TNF, was capable of electron (as well as hole) transport [30a, 45]. Electron-transporting materials have received considerable study though none has performed well enough for current practical applications [3q]. Now the CTM is an electron acceptor, the charge carrier is an electron in the lowest unoccupied molecular orbital (LUMO), and the charge transport process is again a self-exchange reaction (Eq. (2)).

Materials that transport electrons passably tend to have rather low (anodic) reduction potentials (ca. -0.1 to -0.6 V vs. SCE) [46]. This is presumably to prevent electron trapping by O_2 , although this explanation has not actually been proven. The requirements on solubility, etc., are the same as for hole-transporting materials.

Instead of dissolving a CTM in a polymer, one can incorporate it in the polymer chain or as a pendant group. The archetypal example is poly(*N*-vinylcarbazole) [27]. A more recent example is poly(tetraphenylbenzidine) [47]. Many other examples can be found in the literature [48]. While the mechanical properties and thermal stability of such polymeric transport materials can be superior to those of the corresponding doped polymers, the charge transport properties are often inferior [48d,e,h]. Polymers of a quite different kind, the polysilylenes and polygermylenes (or “polysilanes” and “polygermanes”) exhibit excellent charge transport [48h,49]. These polymers transport holes through the silicon or germanium backbone.

2.6.2 Charge Carrier Mobility

Experimental method and typical results

Charge transport in a practical charge transport layer (CTL) must satisfy two basic requirements. First, charge carriers must be mobile enough to cross the CTL in the time available. We will focus on this aspect. Second, deep trapping (such that the

carriers are detained by several seconds or longer) must be rare. Although this latter aspect is equally critical, relatively little mechanistic information has been published.

Almost all commercial organic photoreceptors employ hole-transporting molecularly doped polymers as CTLs, and only a few kinds of hole-transporting CTMs and host polymers are widely used [3q]. Nevertheless, a fairly wide range of materials has been investigated, to elucidate the physics and chemistry governing the charge transport process and/or search for useful new materials. These include both hole- and electron-transporting CTM and a considerable variety of host polymers. In addition, many of the CTM can be prepared as thermally stable monocomponent glasses, and the transport properties of these glasses have also been examined extensively. The underlying physics appears to be the same, and we shall include both molecularly doped polymers and amorphous molecular glasses under the general rubric of "amorphous molecular solids". Some of the same hole-transporting glasses are used in organic light-emitting diodes; however, the electron-transporting glasses discussed below generally have too anodic a reduction potential, or too large an electron affinity, for that purpose. On the other hand, we will not discuss transport in molecular *crystals*. There have been only a few, cursory, studies of crystals chemically analogous to our CTM [50]. However, transport in most organic molecular crystals is qualitatively different from that in the amorphous systems in that it is generally slower by orders of magnitude, and depends much more strongly on electric field strength and temperature in amorphous media [14a].

In a given material, at a given temperature (T) and electric field strength (E), charge carriers move with some average velocity $v(E, T)$. In a crystalline material, usually $v \propto E$, and one can characterize transport succinctly in terms of the proportionality constant, the mobility $\mu(T) = v/E$. In amorphous materials, v usually increases superlinearly with increasing E , but it is still customary to describe transport in terms of the mobility, which now depends on E as well as T , namely as $\mu(E, T)$. Most studies have concentrated on these dependences and the influence of chemical composition upon them.

Mobility is most commonly measured using a time-of-flight experiment (Figure 28a). A film of the material of interest is sandwiched between two electrodes. Blocking layers may be utilized to prevent dark charge injection. At least one electrode is semitransparent. A short pulse of charge carriers is injected briefly from one side, an electric field drives them across the film, and the time required to reach the other side (the transit time, t_t) indicates their velocity, $v = d/t_t$, where d is the thickness of the film. Most commonly, the carriers are launched by a relatively thin charge generation layer (CGL) that is "turned on" briefly by a flash of visible light. It is sometimes possible to omit the CGL and generate the carriers in the transport material itself, using a flash of shallowly penetrating ultraviolet light. It is also possible to use an electron beam [51], or an injecting contact activated by a voltage pulse [47b, 52]. The electric field is supplied by a voltage V applied between the electrodes. The film is usually between 1 and 30 μm thick, the applied voltage is usually several tens or hundreds of volts, and the resulting field strength ($E = V/d$) is usually between 10^4 and 10^6 V cm^{-1} . As the carriers cross the film, the external circuit must supply charge to the electrodes in order to hold V constant. The corresponding current is proportional to the number of carriers and their average

Figure 28. a) A schematic of a time-of-flight experiment. A multilayer sandwich is constructed by depositing the CTL, and other layers (CGL for example) as desired, on a suitable substrate. One electrode is connected to a power supply and the other is connected to ground via a load resistor. The voltage applied by the power supply produces a uniform electric field in the sample. A pulsed exposure generates charge carriers which cross the sample under the influence of the applied field. As they move, current flows through the load resistor to ground and a voltage signal, generated across the resistor, is recorded. The signal is proportional to the number and average velocity of the charge carriers. b) Idealized current (I) signal vs. time (t) from a time-of-flight experiment. The current rises from zero when holes are generated ($t = 0$), remains constant as they drift across the CTL at a constant velocity, and drops back to zero when they reach the collecting electrode (t_i , the transit time or time of flight).

velocity. Recording of this current monitors the progress of the charge carriers as they cross the film. The current begins when they are launched and it ceases when all have reached the collecting electrode. This experiment is repeated over a range of field strengths and temperatures. The field strength usually ranges from the highest value that does not risk catastrophic electrical breakdown of the sample, down to the lowest value at which an adequate signal can be obtained. The temperature usually ranges from a high value near the glass transition temperature, where the sample begins to soften, down to the lowest value at which data can be obtained over a significant range of field strengths.

An ideal time-of-flight signal is shown in Figure 28(b), and real signals are shown in Figure 29. The signal in Figure 29(a) approaches the ideal. However, there is an initial narrow spike of undetermined origin, a brief period of rising current before the steady-state plateau, and a final "tail" of significant duration. The initial spike and the final tail are general phenomena; the rise to the plateau may be an experimental artifact. The end of the plateau marks the time at which holes begin to reach the collecting electrode. The falling tail represents the arrival of additional holes, and the baseline is reached eventually, when all holes have been collected. Thus, there is some spread in the times that holes require to cross the sample. The end of the plateau (t_i in Figure 29a) marks the transit time of the fastest holes, whereas the point at which the current has fallen to half of its plateau value ($t_{1/2}$) represents, loosely speaking, the transit time of an "average" hole. Most of the data discussed below use t_i as the transit time, even though $t_{1/2}$ is a more realistic indication of how rapidly charge is transported by the sample [53]. Other operational definitions of the transit time have been proposed [54]. Figure 29(b) shows a more typical signal. The spike and the tail are broader, and the plateau (in this case) is not entirely flat. The end of the plateau is not abrupt, and the transit time is defined operationally by the crossing of tangents drawn to the plateau (where it is closest to level) and the tail (where it is steepest). In cases where the spike and the tail are much wider and the "plateau" slopes much more steeply, it may be difficult or impossible to discern a "transit time" from linear I - t plots such as Figures 29(a) and 29(b). In such cases, it is frequently possible to discern such a time on a plot of $\ln I$ vs. $\ln t$. As illustrated in Figure 29(c), such a plot often exhibits two approximately linear portions, and the break point between them can be taken as an operationally defined transit time. Generally, this point is identified by a crossing-of-tangents construction like that in Figure 29(b).

In most amorphous molecular solids, the dependence of mobility on electric field strength and temperature has the form illustrated in Figures 30 and 31. Typical field-strength data at various temperatures are shown in Figure 30. At a given temperature, the mobility increases with increasing field strength. With increasing temperature, the mobility increases and the field dependence weakens. The non-linear scales of E and μ are chosen to illustrate that $\ln \mu$ (or $\log \mu$) is usually a linear function of $E^{1/2}$ (Eq. (3)), or μ is an exponential function of $E^{1/2}$ (Eq. (4)), over a wide range of field strengths.

$$\ln \mu(E, T) = \ln \mu(0, T) + S(T)E^{1/2} \quad (3)$$

$$\mu(E, T) = \mu(0, T) \exp(S(T)E^{1/2}) \quad (4)$$

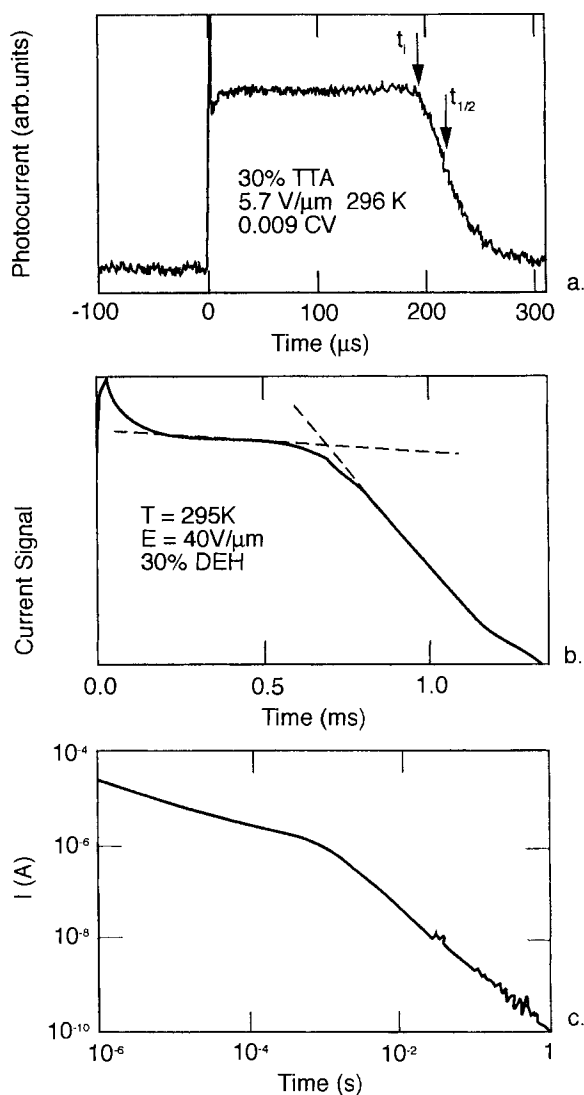

Figure 29. Representative time-of-flight signals for hole transport. a) tri-*p*-tolylamine (TTA) (30 wt.%) in polystyrene. (Reprinted with permission from Ref. [60b].) Two operational definitions of the transit time are indicated by t_i and $t_{1/2}$. b) *p*-Diethylamino-benzaldehyde diphenylhydrazone (DEH) (30 wt.%) in bisphenol-A polycarbonate. (Reprinted with permission from Ref. [60i].) c) A polysiloxane with *N*-alkylcarbazole pendant groups. (Reprinted with permission from Ref. [72g].)

The entire data set, $\mu(E, T)$, can be summarized by the intercept, $\mu(0, T)$, and slope, $S(T)$, as functions of temperature. A typical temperature dependence of $\mu(0, T)$ is illustrated in Figure 31. While the data may be described qualitatively as “activated”, μ exponential in T^{-1} , the dependence is actually somewhat stronger, μ exponential in T^{-2} , as if there were a temperature-dependent activation energy. Whenever the data permit one to judge between T^{-1} and T^{-2} , an exponential dependence on T^{-2} is usually the better description. This dependence can be characterized by its $T \rightarrow \infty$ limit, μ_0 (a hypothetical mobility at infinite temperature), and a slope T_0^{-2} (where T_0 may be viewed as a characteristic temperature) (Eq. (5)).

Figure 30. Mobility, μ , plotted linearly in $\ln \mu$, as a function of electric field strength (E), plotted as $E^{1/2}$, for holes in tri-*p*-tolylamine (TTA) (40 wt.%) in bisphenol-A polycarbonate. The range of field strengths is approximately 10^4 – 10^6 V cm $^{-1}$ (1–100 V μ m $^{-1}$). The mobility depends exponentially on $E^{1/2}$. With increasing temperature, the overall magnitude of μ increases while the dependence on E weakens. These dependences are observed in nearly all amorphous molecular solids. (Reprinted with permission from Ref. [73r].)

Figure 31. Temperature (T) dependence of the “zero-field mobility”, $\mu(0, T)$, for electron transport in 4-*n*-butoxycarbonyl-9-fluorenylidene malononitrile (BCMF) (30 wt.%) in a polyester. The data are plotted as $\ln \mu$ vs. T^{-2} . (Reprinted with permission from Ref. [60j].)

$$\mu(0, T) = \mu_0 \exp(-(T_0/T)^2) \quad (5)$$

The temperature dependence of the slope parameter, $S(T)$, is illustrated in Figure 32. With increasing temperature, $S(T)$ decreases in a manner that is usually a linear function of T^{-2} .

The mobility depends strongly on the concentration of the charge transport material (CTM). Figure 33 illustrates this dependence at room temperature for hole transport in *N*-isopropylcarbazole (NIPC)-doped bisphenol-A polycarbonate from

Figure 32. Field-dependence parameter S vs. temperature (T), plotted linearly in T^{-2} for hole transport in tri-*p*-tolylamine (TTA) (40 wt.%) -doped bisphenol-A polycarbonate. (Adapted from Ref. [73r].)

Figure 33. Dependence of the mobility on CTM concentration: mobility of holes (μ) in *N*-isopropylcarbazole (NIPC)-doped bisphenol-A polycarbonate as a function of field-strength (E), plotted as $E^{1/2}$, for a) 9 %, b) 17 %, c) 23 %, d) 29 %, e) 33 %, and f) 38 % NIPC by weight. (Reprinted with permission from Ref. [51].)

Figure 34. Dependence of the overall-magnitude parameter μ_0 on separation between NIPC molecules (ρ) in NIPC-doped bisphenol-A polycarbonate. The slowly varying factor ρ^{-2} compensates for variation of the average hopping distance. Data taken from Ref. [51].

9 wt.% CTM (below the “practical” concentration range) up to 38 wt.% (approximately the solubility limit) [51]. The functional form of the field and temperature dependences does not change over this range of concentration, and the only quantitative parameter that varies strongly is the overall magnitude of the mobility μ_0 . To illustrate this dependence, in Figure 34, μ_0 is plotted vs. an “average” separation between CTM molecules, ρ . The distance ρ is defined such that the concentration of CTM is one molecule per volume ρ^3 .

One other compositional effect is exceedingly significant. Given a doped polymer in which the CTM and the polymer host are relatively nonpolar, and a similar material in which a highly polar species is present, the mobility in the polar system is usually much smaller and more strongly dependent on field strength and temperature. Figure 35 illustrates this trend with the zero-field mobilities, $\mu(0, T)$, plotted as functions of temperature, for tri-*p*-tolylamine (TTA) in two polymers [55a]. The dipole moment of TTA is small, ~ 0.9 D [55b]. The dipole moment of polystyrene, 0.4 D per repeat unit [55c], is much smaller than that of poly(4-chlorostyrene), ~ 1.9 D per repeat unit, approximated by the dipole moment of *p*-chlorotoluene [55d]. The mobility in the polar host is much smaller and depends much more strongly on temperature. There are many literature examples of the polymer host effect on mobility [55e–k]. Figure 36 provides another illustration, in which TTA/polystyrene is co-doped with equimolar, small amounts (~ 2 wt.%) of highly polar additives [56a].

Figure 35. Zero-field mobility (μ) for hole transport in TTA (40 wt.%) -doped polystyrene (above) and poly(*p*-chlorostyrene) (below), shown as functions of temperature (T , plotted as T^{-2}). (Reprinted with permission from Ref. [55a].)

The larger the dipole moment of the additive, the lower the mobility and the steeper its field dependence becomes. The literature has many examples of the effect of polar third components [55g, 56a–f]. If the dominant polar component is a hole-transporting CTM itself, the mobility largely correlates with its dipole moment, even across various chemical families (Figure 37) [56g–m].

Qualitative explanations

Before presenting some additional experimental observations, we pause to discuss, qualitatively, how the foregoing trends and dependences may be understood. (A quantitative theory of charge transport in amorphous molecular solids will be discussed later.) In any charge transport process, whether the carriers are electronic or ionic, and whether the medium is crystalline, amorphous, or fluid, each individual carrier undergoes a random walk in which there is a preference (large or small, de-

Figure 36. Mobility (μ) and its dependence on field strength (E) for TTA (30 wt.%) -doped polystyrene (broken line) and TTA-doped polystyrene containing small amounts of polar additives. Their dipole moments are indicated beside the corresponding lines. The concentration of each additive was 1.3×10^{20} molecules cm^{-3} , corresponding to 2–4 wt. %: *p*-dinitrobenzene (0.6 D), *m*-dicyanobenzene (3.6 D), 1-cyanonaphthalene (3.9 D), 3-nitrobiphenyl (4.0 D), *o*-dicyanobenzene (5.7 D), and 4-*t*-amylphthalonitrile (6.6 D). (Reprinted with permission from Ref. [56a].)

pending on the field strength) for steps in the forward direction (Figure 38). In an amorphous molecular solid, the random walk may be viewed as a sequence of hops (electron transfer reactions, Eq. (1) or (2)) between nearby sites (CTMs). At each site, the carrier has a “site energy” equivalent to the energetic cost of producing the cation or anion of the corresponding CTM (i.e., its solid-state ionization potential or electron affinity). With this definition, thermodynamics favors occupancy of low-energy sites for hole, as well as electron, transport. For electrons, a low-energy site has a low-energy LUMO; for holes, it has a high-energy HOMO. The site energy varies randomly from site to site, because an amorphous molecular solid is (by

Figure 37. Hole mobility (μ) vs. dipole moment of the charge transport material (CTM) (50 wt.%) in a polycarbonate host. The CTMs belong to various chemical classes. The field strength was $2.5 \times 10^5 \text{ V cm}^{-1}$. (Reprinted with permission from Ref. [56g].)

Figure 38. Schematic of an amorphous molecular solid with both energetic and geometrical disorder. Each randomly oriented hopping site (CTM) is represented by a disk with the number of concentric rulings representing the energy of a charge carrier. (Site A is relatively shallow; site B is very deep.) Electric field direction is E. See the text for a detailed explanation.

definition) disordered, and different CTMs are in different environments. This factor is known as energetic, or diagonal, disorder. Therefore, each hop generally involves an energy increment, and the hopping rate constant depends on that increment. Since most hops involve sites of different energy, they are only formally self-exchange reactions. Moreover, a charge carrier tends to spend most of its time at relatively low-energy sites. In addition to energetic factors, there are geometrical factors as well. Even if there were no disorder, steps from one site to its nearest neighbors would have different rate constants because of the asymmetric shapes of typical CTMs and their HOMOs or LUMOs. In a disordered material, the relative orientations and separations of near neighbors also vary randomly, a factor known as geometrical, or off-diagonal, disorder.

The distribution of site energies (DOS, for “density of states”) is generally assumed to be Gaussian, with an r.m.s. (root mean square) width several times larger than $k_B T$ (the thermal energy). For qualitative purposes, some important consequences of such a DOS are the following.

- 1) If there were no electric field, the thermal average energy would be deep in the low-energy “tail” of the DOS. In the presence of a field, the steady-state distribution of energies is no longer that of thermal equilibrium. Nevertheless, as it crosses the sample, a carrier spends most of its time in such low-energy sites.
- 2) Those sites are sufficiently rare, and hence sufficiently far apart, that a carrier cannot simply hop from one to another. Rather, it must first hop to a nearby site of higher energy (in the central portion of the DOS) and undergo further hops among other sites of similar energy, before eventually finding another low-energy site.
- 3) As the temperature decreases, the average energy decreases, i.e., carriers sink deeper and deeper into the tail of the DOS.
- 4) Hops from deep sites to nearby, higher-energy sites contribute to the activation energy for transport. At lower and lower temperature, that contribution increases because a carrier spends most of its time in deeper and deeper sites. The apparent temperature-dependent activation energy mentioned in conjunction with Eq. (5) is easily understood on this basis. (Of course, any reorganization energy for the electron transfer process may also contribute to the temperature dependence.)
- 5) The energy differences among nearby sites are altered by the presence of an electric field, and, therefore, so are the hopping rate constants. It is plausible, if not entirely obvious, that energetic disorder should generally make the mobility more strongly field-dependent.
- 6) Suppose that, at the start of a time-of-flight experiment, carriers are injected into states in the center of the DOS. They would then take many rapid steps among sites of similar energy before coming to (temporary) rest at a rare, low-energy site. This initial, rapid motion is one possible explanation of the initial spike in the photocurrent signal (Figure 29). The plateau represents a subsequent steady state.
- 7) The time that an individual carrier requires to cross the sample is the sum of the times (residence times) that it spends at each site along the way, which is

approximately equal to the sum of times spent at a few very deep sites. Different carriers encounter different numbers of such sites, and since these numbers are small, the *relative* variation among them is large. The extended tail of the time-of-flight signal (Figure 29) is a consequence.

The concentration dependence of the mobility is also easily understood. The CTMs are not in close contact, so electron transfer between them is presumably nonadiabatic [34k], and the rate constant(s) should have roughly an exponential dependence on the distance between molecules. (Adiabatic transport is reported in some systems [57a–c]. However, the interpretation in terms of adiabatic transport requires problematic values for an electron transfer integral and phonon frequency [57b].) The mobility ought to exhibit a similar exponential dependence on the average separation. Indeed, the trendline in Figure 34 has a slope of 1.35 \AA^{-1} , comparable with the rate at which electron transfer rate constants typically vary with intermolecular separation [57d–f]. (The mobility must depend on not only the rate constant(s), but also the average distance ($\sim \rho$) over which a charge carrier moves in an individual electron transfer event. To compensate for this factor, in plots like Figure 34, the abscissa is usually μ or μ_0 divided by a factor such as ρ^2 . Additional divisors are sometimes included, to remove the influence of other presumed theoretical factors (see the section on geometrical disorder, below).)

The influence of polar components can also be understood in terms of energetic disorder. Near any site, there are polar molecules (or moieties) oriented at random, and the electrostatic interactions between their dipole moments and a charge carrier make random contributions to the site energy. Thus, the presence of polar components increases the total energetic disorder (viz. the width of the DOS) and, thereby, the strength of the dependence on temperature and field strength. Most probably, the dipoles reorient somewhat in response to the presence of a charge at that site, and the corresponding reorganization energy should also contribute to the temperature dependence. This contribution is probably minor, because the materials are rigid in the temperature range of interest. The dielectric constants of the host polymers are governed by the same ability of the dipoles to reorient, and they are typically small (3.0 for polycarbonate [58a], 2.6 for poly(*p*-chlorostyrene) [58b], 2.6 for poly(methyl methacrylate) [58c]. In cases where they have been evaluated, the dielectric constants of the doped polymers are also low [56d,1]. (An early assertion that a small amount of a highly polar additive dramatically increases the dielectric constant [56b] could not be reproduced [56d].)

The Gaussian Disorder Model

A simple model, the Gaussian Disorder Model of Bässler and co-workers, has been very useful in rationalizing charge transport data on many amorphous molecular solids [59]. Its present version consists of the following assumptions.

- 1) Transport sites are arrayed on the points of a simple cubic lattice. The lattice parameter is denoted a .

- 2) The site energies ε_i^0 (before application of an electric field) belong to a Gaussian distribution characterized by its r.m.s. width (standard deviation, σ), (the term “variance”, often used synonymously, more properly refers to σ^2) with no correlation between the energies of different sites.
- 3) A wavefunction-overlap parameter, Γ_{ij} , is assigned to each pair of sites. It is assumed to be a sum of individual-site contributions Γ_i and Γ_j , each belonging to a Gaussian distribution. The values at neighboring sites are uncorrelated. The resulting average value and standard deviation of the Γ_{ij} are denoted $\bar{\Gamma}$ and Σ . This assumption is intended to model geometrical disorder.
- 4) The rate constant for hopping from site i (located at \mathbf{r}_i) to site j (at \mathbf{r}_j) depends on the site energies $\varepsilon_i^0, \varepsilon_j^0$ and the overlap parameter Γ_{ij} according to Eq. (6),

$$v_{ij} = v_0 \exp(-\Gamma_{ij}\mathbf{r}_{ij}/a) \exp(-\beta(\varepsilon_{ij}^0 - q\mathbf{E} \cdot \mathbf{r}_{ij})) \quad (6)$$

where v_0 is an additional constant determining the overall rates, $\beta = (k_B T)^{-1}$, q is the charge of the carrier, $\varepsilon_{ij}^0 = \varepsilon_j^0 - \varepsilon_i^0$, and $\mathbf{r}_{ij} = \mathbf{r}_j - \mathbf{r}_i$.

The consequences of this model have been explored by Monte Carlo simulation [59b]. A model sample is constructed, using a Gaussian random-number generator to assign an ε_i^0 and a Γ_i to each lattice site. A carrier is placed on an arbitrary initial site, and its random walk through the lattice is generated. A random-number generator is used to decide how long the carrier resides at each site and which site it visits next, taking into account the rate constants for various possible hops from this site to nearby sites. This process is repeated for several carriers on a given lattice, then a new sample is constructed and more random walks are generated. The average velocity and other statistics are collected. The results have been summarized by formulas for the zero-field (limiting) mobility (Eq. (7)) and the slope of the field strength (Eq. (8)) as functions of temperature (cf. Eqs. (3)–(5)):

$$\mu(0, T) = \mu_0 \exp(-(\frac{2}{3}\hat{\sigma})^2) \quad (7)$$

$$S(T) = C(\hat{\sigma}^2 - \hat{\Sigma}^2) \quad (8)$$

Here, μ_0 is a constant (proportional to v_0); $\hat{\sigma} = \sigma/k_B T$; $\hat{\Sigma} = \Sigma$ or 1.5, whichever is greater; and $C = 2.9 \times 10^{-4} \text{ cm}^{1/2} \text{ V}^{-1/2}$.

Equations (7) and (8) have been used to fit the data on many amorphous molecular solids. They reproduce the T^{-2} temperature dependence of the mobility that is often observed, both at zero [Eq. (5)] and nonzero field strength [60a]. The slope of a plot of $\mu(0, T)$ vs. T^{-2} (see Figures 31, 35) can be used to evaluate σ . Equation (8) also predicts a T^{-2} dependence for the slope parameter, viz. $S(T) = [C(\sigma/k_B)^2]T^{-2} + \text{constant}$ (see Eq. (4)), and this dependence is consistent with the experimental data. For the example shown in Figure 32, the slope of a plot of $S(T)$ vs. T^{-2} can be combined with the value of σ evaluated from the temperature dependence of $\mu(0, T)$ to evaluate the proportionality constant C . The result in that case is $2.6 \times 10^{-4} \text{ cm}^{1/2} \text{ V}^{-1/2}$, in remarkable agreement with the predicted value of

$C = 2.9 \times 10^{-4} \text{ cm}^{1/2} \text{ V}^{-1/2}$. This level of agreement is typical although C values as low as 1.6×10^{-4} and as high as $4.4 \times 10^{-4} \text{ cm}^{1/2} \text{ V}^{-1/2}$ have been reported [60b,c].

Another prediction of the model is the following. Imagine two doped polymers in which the identity, concentration, and packing of the CTM are the same (i.e., the geometrical disorder is the same) but the degree of energetic disorder is different. The mobility in the two materials should be described by the same values of μ_0 and Σ . Data shown in Figure 35 illustrate approximately the anticipated behavior. Over the experimental temperature range, the zero-field mobilities differ by orders of magnitude. Nevertheless, when the data are analyzed according to Eq. (7), the resulting values of μ_0 differ by only a factor of approximately 3! (The values of μ_0 are 0.042 in polystyrene and 0.013 in poly(*p*-chlorostyrene) [55a].) Numerous similar cases are known [55i, 56l, 60]. This comparison is based on the assumption that the arrangement of the CTM is the same in the two materials (or that it does not matter much). Molecular packing in amorphous solids is neither controlled nor well understood; so, it is not surprising that some counterexamples are also known, particularly in comparisons between structurally very different host polymers [55j, 60h].

As described above, the effect of polar components has been ascribed to a contribution of random charge–dipole interactions to the overall disorder. When data on polar and nonpolar systems are compared using the Gaussian Disorder Model, the polar systems generally have larger values of σ . In fact, the difference between well-matched polar and nonpolar systems, such as those illustrated in Figure 35, can be reproduced at least semiquantitatively on the following basis. In the polar system, assume that the charge–dipole contributions to the site energies are uncorrelated with the remaining (“nondipolar”) contributions, and assume that the nondipolar contributions are the same in the two systems. Further, to model the charge–dipole interactions, consider a point charge surrounded by a simple cubic lattice, with randomly oriented point dipoles occupying random lattice points [61]. Then the predicted relationship between σ values [eV] for the polar and nonpolar materials, σ_p and σ_n , is given by Eqs. (9) and (10),

$$\sigma_p^2 - \sigma_n^2 = \sigma_d^2 \quad (9)$$

$$\sigma_d[\text{eV}] = 0.173 p \kappa^{-1} M^{1/2} (a')^{-1/2} \quad (10)$$

where p and M are the dipole moment [Debyes] and concentration [mol L^{-1}] of the polar component, κ is the relative dielectric constant of the doped polymer, and a' is the lattice constant [\AA] for the model lattice [61d]. If the polar component is the CTM, $a = a'$. If it is an additional dopant or part of the polymer, the best choice of a' is generally not equal to a . The result is model-dependent, but weakly so, provided that a' is chosen to be of molecular dimensions. For example, the temperature dependences shown in Figure 35 imply σ values of 0.082 and 0.122 eV for TTA in polystyrene and poly(*p*-chlorostyrene), respectively, whence $\sigma_d = 0.086$ eV. Using Eq. (10) with $p = 1.9$ D [55d] and $M = 4.3 \text{ mol L}^{-1}$ for chlorophenyl moieties, neglecting the contribution of less polar components, and taking $\kappa = 3$ (a reasonable value for the low-frequency dielectric constant, but the actual value unknown), and $a' = 7 \text{ \AA}$ (the sum of estimated radii of a TTA molecule and a chlorostyrene unit)

gives a remarkably similar value, 0.091 eV. This degree of agreement is surely fortuitous; only rough agreement should be expected from so simple a model. In addition to the use of point charges and dipoles and a uniform, cubic lattice, the dielectric constant is introduced in an ad hoc manner. Moreover, the most appropriate value of κ may not be that of the rigid amorphous solid, which is in any case unknown. Nevertheless, even rough agreement offers some confirmation of the Gaussian Disorder Model as a whole, as well as its explanation of the effect of polar components. The literature offers numerous examples, although some comparisons of different materials using an equivalent of Eq. (10) need to be adjusted to account for differences in molecular weight [55a,i, 56l,m, 60a,e,g, 62a-c].

Despite the considerable success of Eq. (7) in consistently rationalizing mobility data in many systems, the Gaussian Disorder Model misses the mark in one major way. The field-strength (E) dependence predicted for a realistic value of $\hat{\sigma}$ (3.0, approximately the smallest $\hat{\sigma}$ ever encountered in practice) and various values of Σ is shown in Figure 39 [63a,b]. Only for strong fields (sometimes only above 10^6 V cm^{-1}) are the results adequately described as linear functions of $E^{1/2}$, whereas experimentally this linearity usually extends to the lowest values of E accessible (sometimes as low as 10^4 V cm^{-1}) [60b, 63c,d]. It was initially proposed that the

Figure 39. Field-strength (E) dependence of the mobility (μ) predicted by the Gaussian Disorder Model. (Reprinted with permission from Ref. [63b].)

discrepancy at low E was due to different operational definitions of mobility in the simulations and experiments [63b]; however, further experimental observations make this rationalization unlikely [60b]. The Slope values in Eq. (8) are taken from a fit to just the high-field linear portion [63b]. Given that the field dependence is not reproduced properly over the typical experimental range, it may well be fortuitous that the experimental slope parameter C agrees so well with the value predicted from this fit [$2.9 \times 10^{-4} \text{ cm}^{1/2} \text{ V}^{-1/2}$]. The observed value of C is $\sim (e\rho/k_{\text{B}}T)^{1/2}$, a rather natural scaling factor for $E^{1/2}$ [63e]. In fact, the quality of the agreement deteriorates somewhat when the experimental data are reanalyzed with a more exact theory (Eq. (12), below). Moreover, the model of geometrical disorder that gives rise to this prediction is quite arbitrary, other simple models give different field dependences [63e], and a different field dependence also arises if an alternative, equally plausible dependence on site energies is assumed for the hopping rate constant [63f]. There is no particular reason to favor one model over another. The assumption of a Gaussian distribution of Γ_{ij} values is, in fact, not very plausible. It is equivalent to the assumption that the orbitals involved in electron transfer are a) spherically symmetric and b) characterized exclusively by variation of their “orbital radii” via the site parameters Γ_i . Neither assumption is particularly realistic, and assumption b) entails an unphysical correlation among the prefactors ν_{ij} for hops originating at the same site (i) [63e]. Geometrical disorder represents the distribution of intermolecular electron transfer matrix elements (V) among nearby pairs of CTMs, and V has a complicated dependence on intermolecular separation and mutual orientation [63g]. The resulting distribution of V has not been evaluated. A promising alternative explanation of the specific form of the field dependence will be sketched in the next section.

Although the general outlines of the Gaussian Disorder Model are probably correct, it is important to note some additional concerns.

- 1) A Gaussian distribution of site energies is expected when each site energy is the sum of many independent contributions of comparable size. The model of dipolar effects underlying Eq. (10) indeed predicts such a distribution, essentially because the charge–dipole interaction is relatively long-ranged and, indeed, many dipoles affect the energy of a given site [61d]. The energetic disorder in a rigid medium is roughly a frozen-in version of the energy level fluctuation that occurs rapidly in a fluid medium. The Gaussian distribution that is assumed to describe static disorder is analogous to the parabolic distribution of (free) energies ascribed to fluctuations in a fluid solution [64a,b]. However, in materials lacking large dipole moments, the relevant interactions of a charge carrier with nearby molecules (charge–polarizability, charge–quadrupole, etc.) are relatively short-ranged, and there may not be enough independent contributions to yield a Gaussian distribution of site energies, especially in the low-energy tail where charge carriers spend most of the time.
- 2) An independent estimate (i.e., spectroscopic) of the magnitude of the energetic disorder in these materials is needed. To date, σ has been largely a fitting parameter. The fact that a theoretical estimate of the dipolar contribution (σ_{d}) agrees reasonably well with experiment is encouraging, but not definitive.

- 3) The specific energy dependence of the microscopic rate constant, Eq. (6), is not of the form usually encountered in electron-transfer theory [64c,d], nor is it consistent with the current understanding of charge transport in molecular crystals [64e]. Equation (6) was originally derived to represent trap-to-trap hopping in crystalline semiconductors at cryogenic temperatures [64f], and it is not obviously applicable to molecular solids around room temperature [64g,h]. The literature has examples of calculations employing other functional forms for the microscopic rate constants [63f, 64e,i–n].
- 4) The simulations themselves were done using fixed values of the parameters, $a = 6 \text{ \AA}$ and $\Gamma = 10$. The values that would be appropriate to model a given system depend on the concentration of CTM (6 \AA is invariably too small), and the results, e.g., the value the factor of $2/3$ in Eq. (7), depend on these parameters [64o].
- 5) The simulation results are more accurately represented by a formula that differs somewhat from Eqs. (7) and (8), i.e., Eqs. (11) and (12),

$$\mu(0, T) = \frac{T_r}{T} \mu_0 \exp(-(\frac{2}{3}\hat{\sigma})^2) \quad (11)$$

$$S(T) = C(\hat{\sigma}^2 - \hat{\Sigma}^2) \left(\frac{T_r}{T} \right)^{1/2} \quad (12)$$

where T_r is a reference temperature (e.g., the temperature for which the simulations were actually done, 295 K) [64H]. Use of these formulas, instead of Eqs. (7) and (8), gives very similar values of μ_0 , σ , and Σ , but significantly different values of C [56l, 60b, 64H, 64p].

The Correlated Disorder Model

The ubiquitous dependence of the mobility on field strength, exponential in $E^{1/2}$ (Figure 30) has puzzled researchers for decades [45, 63c,d]. Such a dependence can arise if the material contains charged traps (the Poole–Frenkel effect) [3q], but this explanation seems implausible for the following reason. In most amorphous molecular solids, such traps would have to be accidental impurities; their concentration would most likely vary from batch to batch or from laboratory to laboratory, and so should the observed mobility values. While there are variations in measured values from one laboratory to another, they are usually not severe enough to support this explanation. As indicated above, the Gaussian Disorder Model fails to reproduce the E dependence at low field strengths, and the reason may be obvious in hindsight. The observed $E^{1/2}$ dependence sometimes extends below 10^4 V cm^{-1} [60b, 63c,d]. The relative energies of two sites $\sim 10 \text{ \AA}$ apart (a typical near-neighbor separation) are shifted by no more than 5 meV by a field of even, say, $5 \times 10^4 \text{ V cm}^{-1}$, and it is hard to see how a shift that is so small relative to $k_B T$ can have a nonlinear influence on charge-carrier dynamics. What is needed is an influence that somehow introduces a greater length scale, and such an influence has recently been proposed.

In the original Gaussian Disorder Model, it was assumed that the energy of any site was uncorrelated with the energy of any other site. A correlation among the energies of sites over distances longer than the average intersite separation can profoundly alter the field dependence of the mobility [65a,b]. Charge–dipole interactions necessarily lead to such a correlation. The interaction of a charge and a dipole, itself, has a rather long range. The energy of interaction of a point charge and a point dipole at a distance R is proportional to R^{-2} . Although this quantity decreases fairly rapidly with increasing distance, the number of dipoles at distances between R and $R + \delta$ increases as R^2 . It is important to note that the correlation of interest is not between the orientations of neighboring dipoles (which may also occur), but between the contributions of distant dipoles to the energies of sites that are not very far apart. The energy at a given site includes significant contributions from dipoles that are far away (relative to the average intersite spacing), and the same dipoles make approximately equal contributions to the energies at other sites near the first one. Consequently, the energies at different sites are correlated, and the length scale of the correlation is greater than the intersite spacing [65a,c,d].

The Correlated Disorder Model of Novikov et al. is like the Gaussian Disorder Model except that each lattice point bears a randomly oriented point dipole as well as a transport site, and the site energy is evaluated by explicitly calculating the energy of a point charge in the presence of the lattice of dipoles [63f]. Thus, the correlations between energies at different sites are built into the model. Simulations of charge-carrier motion on this lattice are able to reproduce the observed $E^{1/2}$ dependence over most of the accessible range of field strengths [63f, 64i, 65c,e,m]. An example is shown in Figure 40. An explanation of how this correlation among the energies of neighboring sites leads specifically to an $E^{1/2}$ dependence of the mobility has been proposed [65b,f]. Based on such simulations, a new formula has been proposed to replace Eqs. (7) and (8) for fitting experimental data [63f, 65g].

Although this model offers a satisfying explanation of the $E^{1/2}$ dependence, it applies only to materials in which interactions between a charge carrier and static dipoles are important. In relatively nonpolar materials, the dominant sources of disorder are probably the interactions of a charge carrier with dipole moments that it induces in its environment [59a], interactions with static higher-order multipoles [65g], and perhaps variations of the ionization potential or electron affinity associated with variations in conformation of the charge-transporting molecule [60c, 65h]. These contributions are all of shorter range than the charge–static dipole interaction and can be expected to give different field-strength dependences. It remains to be seen whether the differences are large enough to be tested, or small enough that the “ \sqrt{E} ” problem has finally been solved [65g,i]. Recent literature has other proposals about the origin of the $E^{1/2}$ field dependence [64j,k, 65j–l].

Recent literature has many examples of theoretical and experimental estimates of the nondipolar (“van der Waals”) component [56m, 59a, 60a,e, 62b,c, 63f, 66a–l]. These estimates may need revision in light of the new understanding of how charge–dipole interactions affect the mobility.

Figure 40. Mobility (μ , plotted as $\ln \mu$) vs. field strength (E , plotted on a scale proportional to $E^{1/2}$) as predicted by the Correlated Disorder Model for DOS of various r.m.s. widths σ_d . The disorder is assumed to arise purely from random charge-dipole interactions. The lattice parameter is a . For $a = 10 \text{ \AA}$ and $\sigma_d = 0.1 \text{ eV}$, $eaE/\sigma_d = 1$ corresponds to a field strength of 10^6 V cm^{-1} . (Reprinted with permission from Ref. [63f].)

The influence of polar components or dipolar disorder

Since dipolar disorder (or, empirically, the presence of polar components) is a major factor governing the mobility, it is worthwhile to make several additional comments on the subject.

To a remarkable degree, it has been possible to correlate the mobility in a given hole-transporting CTM with its net dipole moment, as illustrated in Figure 37. (When molecules with different chemical structures and molecular weights are compared at “equal concentrations”, however, there is some question concerning what measure of concentration to hold constant—weight fraction, molar concentration, etc. [55b].) There are exceptions, CTMs with small dipole moments that, nevertheless, exhibit low mobility for reasons that have not been identified [55b]. It is frequently not possible to determine whether the correlation is with net dipole moment or the overall content of polar groups [55b], and there are cases where the

Figure 41. Correlation of mobilities (μ), in the limit of zero-field strength, with the net dipole moment of hole-transporting molecules doped into polystyrene. The hole-transporting unit is essentially the same in each case, a substituted triphenylamine, and it is present at the same molar concentration. The mobility is much reduced for the molecules whose dipole moments are larger because they contain polar substituents (ESTER, BROMO). It is essentially independent of dipole moment for the molecules whose dipole moments are larger just because several triarylamine groups with small dipole moments are chemically linked (TTA, TAPC, TETRA). (Reprinted with permission from Ref. [55b].)

correlation fails for rather obvious reasons. For example, Figure 41 presents a series of five triarylmines at equal molar concentrations of the charge-transporting moiety in a nonpolar host. Two, 4-[bis-(4-methylphenyl)amino]benzenepropanoic acid ethyl ester (ESTER), and 4-bromo-4',4''-dimethyltriphenylamine (BROMO), contain fairly polar groups and exhibit lower mobilities. The remaining three are a monomer (TTA), a dimer (TAPC), and a tetramer (TETRA) of essentially the same triarylamine moiety (Scheme 2). For these three, the concentrations of (weakly) polar moieties are the same, and the main reason that the larger molecules have larger dipole moments is probably just the random addition of several triarylamine group moments [55b].

Figure 42. The mobility of electrons in this family of compounds is affected by the presence of additional polar substituents ($-\text{CF}_3$ substitution for $-\text{H}$ on a phenyl sidegroup), rather than the net dipole moment. In contrast to the order of the dipole moments, the mobilities (μ) in **M** and **P** are nearly equal, and they are much lower, and more strongly dependent on electric field strength (E), than the mobility in **PTS**. (Reprinted with permission from Ref. [64p].)

Electron-transporting molecules generally contain multiple highly-polar, electron-withdrawing substituents in order to adjust their electron affinities. The mobilities in such materials are usually relatively low, and the presence of such polar groups is likely to be a contributing factor, even when they are arranged in such a way that the net dipole moment is zero, e.g., *N,N'*-bis(1,2-dimethylpropyl)-1,4,5,8-naphthalenetetracarboxylic diimide (NTDI) (Scheme 3) or 3,5-dimethyl-3',5'-diisopropyl-4,4'-diphenylquinone (DPQ) (Scheme 3) [67]. One case where the presence of polar groups is demonstrably important, regardless of whether their contributions to the net dipole moment partially cancel or reinforce each other, is illustrated in Figure 42 [64p]. Studies were carried out on materials related to 1,1-dioxo-2-(4-methylphenyl)-6-phenyl-4-(dicyanomethylidene)thiopyran (**PTS**) (Scheme 3). Compounds **M** [1,1-dioxo-2,6-bis(3-trifluoromethylphenyl)-4-(dicyanomethylidene)thiopyran] and **P** [1,1-dioxo-2,6-bis(4-trifluoromethylphenyl)-4-(dicyanomethylidene)thiopyran] contain CF_3 groups (~ 2.6 D), located so that the net dipole moments are in the order **M** > **PTS** > **P**. Yet, the mobilities are in the order **PTS** \gg **P** \approx **M**, and the energetic disorder parameters σ are in the corresponding (reverse) order (**PTS** < **P** \approx **M**).

There is presently no theoretical estimate of the effect of *group* dipole moments when they are linked in such a way that their orientations are partially correlated. There has been a preliminary treatment of the case in which they are rigidly linked to form a net quadrupole [65g].

The clearest examples of the influence of polar constituents usually involve materials in which no more than one component has a large dipole moment, such as a relatively nonpolar CTM doped into nonpolar and polar polymers, a nonpolar polymer doped with relatively nonpolar and polar CTMs, or a relatively nonpolar CTM and nonpolar polymer additionally doped with a highly polar additive. Similar effects are sometimes seen when a polar polymer is doped with CTMs having various dipole moments [56g–j, 64p]. Often, however, the mobility in a highly polar CTM is independent of, or only weakly affected by, the nonpolar or polar character of the host polymer [68a–c]. Often, too, for a highly polar CTM, σ is independent of CTM concentration, contrary to what one would expect on the basis of Eq. (10). A possible explanation is the tendency of neighboring dipoles to have antiferroelectrically correlated orientations [61a].

The nonpolar polymer that has received the most attention is polystyrene. A few studies have included alkyl-substituted polystyrenes, and the majority support the assumption that polystyrene is representative of nonpolar aromatic polymers in general [60b,d, 68d]. There are, in addition, a few data on not-very-polar polymers with quite different chemical structures where, at least, the mobilities at room temperature are similar to those in polystyrene [55k].

Geometrical disorder, molecular packing, excimer-forming sites

We have concentrated on the influence of polar components because, to date, it has received the most thorough study and because it appears to be the most important factor determining charge carrier mobility. Certainly the electronic structure and degree of delocalization of the charge-bearing orbital and the packing of the CTM bearing this orbital must have an influence. We turn briefly to these connected subjects.

A priori, even if the total concentration of CTM is held constant, the manner in which a particular species of CTM packs in the polymer host ought to influence the matrix elements (V) governing electron transfer between neighboring molecules (or the distribution of V), and the mobility should be affected. One would expect some change in the overall magnitude of the mobility, represented by μ_0 in Eq. (5), and perhaps in the slope of the field dependence, S in Eq. (4). It is impossible to control the packing, but it should be possible to influence it by use of bulky substituents or by linking CTMs together so that their mutual orientations are constrained. An example of the latter kind is a comparison of tri-*p*-tolylamine (TTA) and TAPC, which is essentially a dimer of TTA (Scheme 2), both in a polystyrene host. In general, in such comparisons one may have to account for differences in energetic disorder that result from differences in the packing of molecular dipoles. This is a particularly favorable case in that none of the materials is very polar and dipolar disorder should be relatively unimportant. Remarkably, at “normal” concentrations (~ 30 and ~ 50 wt.% CTM), the mobilities in the two CTMs are nearly identical (Figure 43). The difficulty with such “potluck” approaches is that there is no

Figure 43. Comparison of the mobilities of holes in polystyrene doped with equivalent molar concentrations of TTA (above, 30 wt.%) and TAPC (below, 33 wt.%) at various field strengths and temperatures. Because the two triarylamine moieties in TAPC are linked, their arrangement should be somewhat different from that in TTA, yet the mobility behavior is nearly identical. At least in this example, differences in molecular packing do not lead to major differences in the mobility. Zero field values are extrapolations. (Reprinted with permission from Ref. [60b].)

way to know how much the chemical differences actually affect the way that the CTM pack. Nevertheless, the data on TTA and TAPC suggest that variations in molecular packing, per se, need not have much effect on the mobility.

At high concentrations, a large part of the geometrical disorder must be associated with the relative orientations of neighboring CTMs. At lower concentrations, a second factor grows in importance: the fact that TTA may be homogeneously dispersed, whereas TAPC (at an equivalent concentration of triarylamine moieties) must consist of pairs of triarylamine moieties, close together, with a greater distance between neighboring *pairs*. Indeed, at lower concentrations, there are substantial differences in the transport behavior of TTA, TAPC, and a tetrameric analog, TETRA, 1,1,5,5-tetrakis(2-methyl-4-di-*p*-tolylamino)phenylpentane (Figure 44) [69a]. At low concentrations of the dimeric and tetrameric species, $\ln \mu$ is no longer a linear function of $E^{1/2}$, nor even a monotonically increasing function. In TETRA at high field strength, not only the mobility but even the *velocity* of the holes decreases with increasing field strength. Other examples where drift velocity decreases with increasing field strength can be found in the literature [60b, 69b]. The stronger the field, the more slowly the carriers progress! Such low-concentration effects are outside the scope of this article but explanations have been proposed [60b, 69a,b], and the effect simulated [64].

There is, at present, no realistic theoretical model of the effect of geometrical disorder. A proper model must take into account the complicated orientation dependence of the matrix element (V) [63g], as well as the distribution of positions and orientations of the CTM. The simple treatment adopted by the Gaussian Disorder Model predicts a dependence of the prefactor mobility (μ_0) on the geometrical disorder parameter Σ , namely $\mu_0 \propto \exp(\frac{1}{2}\Sigma^2)$ [63a], and this relationship has been used often to analyze experimental data. The comparison of TTA and TAPC at low concentrations disagrees with this prediction, and it appears to be untenable a priori anyway [60b, 63c]. A worthy challenge for future work will be to construct a model with enough realism to have predictive value. Recent reports indicate progress in this direction [64l,o].

A “packing effect” that does appear to matter in certain materials is the presence of dimer or excimer-forming sites. These are sites, relatively rare, where two CTM adopt a close, cofacial (sandwich) configuration. The presence of such sites is inferred from the presence, in the fluorescence spectrum of the material, of an “excimer” component attributable to excited states that are trapped at such sites [27e, 70a–c]. The low mobility of holes in poly(*N*-vinylcarbazole) is believed to result from temporary trapping of holes at these sites [44h, 70d]. In fact, among polymers and doped polymers containing an *N*-alkylcarbazole as the hole-transporting moiety, a higher mobility correlates with a lower propensity for excimer emission [70e–g]. There are many recent studies of excimer-forming sites and hole trapping at such sites [71a–h].

Photocurrent tails, dispersive transport, and trapping

In this section, we touch briefly on several additional aspects of charge transport in amorphous molecular solids.

Figure 44. Velocity (v , not mobility) of holes in polystyrene doped with equivalent, low molar concentrations of TTA (6.8 wt.%), TAPC (7.5 wt.%), and TETRA (7.3 wt.%), all at ~ 335 K. Unlike the situation at high concentrations (Figure 43), linking the triarylamine groups in clusters of two (TAPC) or four (TETRA) dramatically affects the transport behavior. In TETRA, at high field strengths (E), the mobility (v/E) drops so rapidly that even the velocity itself decreases with increasing E . (Reprinted with permission from Ref. [69a].)

We have focused on the mobility as the main parameter characterizing charge transport. The photocurrent transients, however, typically extend well past the nominal transit time (t_t), so that the nominal mobility extracted from t_t underestimates the time required for charge to be transported across a photoreceptor film. A proper characterization of a material, therefore, requires some quantity indicating the width of the tail relative to t_t [72a]. As discussed previously, the tail is believed to arise because individual carriers sample various numbers of “slow sites”,

so it offers another window on the microscopic physics underlying the transport process. The literature has many reports of studies of this subject [64j, 72a–f].

We have tacitly assumed that the measured mobility is a well-defined, steady-state, bulk property of a material. This assumption is tenable whenever the photocurrent signal exhibits a broad, flat plateau and a narrow tail, as in Figure 29(a). In this context, the significance of a narrow tail is that most carriers may be described individually by approximately the same time-averaged drift velocity and mobility. Even for the rather well-behaved material represented by Figure 29(b), however, the “plateau” region slopes somewhat, indicating that transport does not reach a steady state during the time of flight. In extreme cases, the “plateau” slopes so steeply that it cannot be distinguished from a “tail”, and one cannot see a break-point to identify as a nominal transit time. In such cases, it is often possible to extract a nominal transit time from a log–log plot, as in Figure 29(c). The significance of this time is limited, however. Roughly speaking, a monotonically decreasing photocurrent implies that (on average) the velocity of the carriers decreases during their passage through the sample. If so, the time required to cross a thicker sample should be more than proportionately longer. That is, this “transit time” should not be proportional to the thickness of the sample, and the corresponding “effective mobility” should decrease with increasing sample thickness. An example is shown in Figure 45 [72g].

Figure 45. Thickness dependence of the effective mobility (μ_{eff}) for hole transport in a material exhibiting dispersive transport. The line represents a power-law dependence. The material is a polysiloxane with a carbazole pendant group. The field strength was $2 \times 10^5 \text{ V cm}^{-1}$, and the temperature 293 K. (Reprinted with permission from Ref. [72g].)

When charge transport fails to reach a steady state during the time available, the most likely reason is that the transit time is dominated by the time required to escape from the slowest site(s) that a carrier encounters as it crosses the sample. Furthermore, the distribution of release times is such that the carrier continues to encounter slower and slower sites as it crosses a sample. Transport under such conditions is called dispersive, and has been the subject of much study since a seminal paper by Scher and Montroll [73a–e]. The term “dispersive” alludes to the wide dispersion in release times and/or the fact that carriers that are injected simultaneously spread out, disperse, to an anomalous extent as they cross the sample. The literature has several examples of studies of this subject in amorphous molecular solids [66b, 73f–h]. Some materials undergo a transition from essentially dispersive transport at low temperatures to essentially nondispersive transport at higher temperatures, and this dispersive-to-nondispersive transition has been the subject of significant attention [73i–p].

It is easy to tell when transport is essentially nondispersive—the current transients approach the ideal, rectangular shape. It is more difficult to tell whether apparently dispersive transport is an intrinsic property of a material. For example, an early study of triphenylamine (TPA)-doped polycarbonate found that the transport was highly dispersive [73q], but later studies of tri-*p*-tolylamine (TTA)-doped polymers revealed relatively nondispersive transport [57b, 73r]. Commercial triphenylamine is typically contaminated with *N,N,N',N'*-tetraphenylbenzidine, which contributes very deep sites for hole transport (hole traps) [73s], whereas as-received TTA is apparently free of such impurities. This is probably the reason why the two, very similar materials appear to have very different transport properties. In fact, when TPA is purified adequately, the transport properties approximate those of TTA [73t].

As illustrated by this example, an impurity can drastically affect charge transport if its solid-state ionization potential is much smaller than that of a hole transport material or its electron affinity is much larger than that of an electron transport material [44b,f, 74a–i,q,r]. An extraordinary species involving the CTM itself can have the same effect, as illustrated by the (presumed) charge-trapping effect of excimer-forming sites in poly(*N*-vinylcarbazole). The effect of relatively small amounts of a hole-trapping “impurity” on the photocurrent transients in a hole-transporting doped polymer is illustrated in Figure 46 [74i]. The hole-transporting material is TTA (40 wt.%) in a polycarbonate host. The “impurity”, 1,1-bis(*p*-diethylaminophenyl)-4,4-diphenyl-1,3-butadiene (BD), has a much smaller solid-state ionization potential (5.11 eV) than does TTA (5.7 eV). With increasing impurity concentration, the duration of the photocurrent transient increases; i.e., holes take longer and longer to cross the sample. Simultaneously, the photocurrent transient that was fairly nondispersive in the absence of the impurity becomes highly dispersive. In this regime, holes encounter traps as they cross the sample, and more traps at higher concentrations, but apparently they do not sample enough traps to establish a steady state between trapping and release. At 1100 ppm, the transient again becomes fairly nondispersive, suggesting that an approximately steady-state condition has been reached. With a further increase in trap concentration, the transient becomes yet less dispersive, while the timescale continues to increase. Between

Figure 46. Photocurrent transients for hole transport in TTA (40 wt.%) doped polycarbonate containing as an added impurity 1,1-bis(*p*-diethylaminophenyl)-4,4-diphenyl-1,3-butadiene (BD) at various concentrations. The current (vertical) scale is arbitrary. The samples were $\sim 16 \mu\text{m}$ thick, the temperature 298 K, and the field strength $3.75 \times 10^5 \text{ V cm}^{-1}$. (Reprinted with permission from Ref. [74j].)

BD concentrations of 0 and 1 %, the transit time increases by a factor of ca. 3000. The corresponding mobility, referred to as the trap-limited mobility, decreases by the same factor, roughly in inverse proportion to the impurity concentration. The decrease is actually somewhat faster, proportional to $(\text{concentration})^{-1.3}$, probably indicating that true steady state has not yet been achieved [53a]. While the outlines of the effect of a charge-trapping impurity seem simple, the details are not [74i]. The literature has several examples of recent work on this subject [44c, 46d, 53a, 65g,i, 74j–o].

2.6.3 Chemical Desiderata for Charge-transporting Materials

As mentioned before, a low ionization potential (cathodic oxidation potential) or a high electron affinity (anodic reduction potential) makes a potential CTM less susceptible to trapping by adventitious impurities. Whether or not charge-trapping

impurities are actually present, however, depends on details of synthesis and ease of purification of the CTM. Furthermore, the CTM must be thermally and photochemically stable to conditions experienced during its lifetime in an electrophotographic printer or copier [3q]. The cation or anion radical of the CTM must be chemically stable, at least in the host polymer. If a compound has a very low ionization potential or a very high electron affinity, and if the radical ion is stable, the compound may be susceptible to contamination by ion-radical salts that increase the dark conductivity of a photoreceptor. In addition, a CTM must be very soluble in a suitable polymer host, but compounds with very low ionization potential or very high electron affinity tend to be quite insoluble. There are conflicting reports as to whether the ionization potential (or electron affinity), per se, matters, at least within the relatively narrow range usually investigated [3q].

Charge-transporting molecules with relatively high carrier mobilities generally lack large net dipole moments or highly polar groups. For electron transport, however, highly polar groups ($-\text{CN}$, $-\text{NO}_2$, $-\text{SO}_2$, etc.) are generally required in order to bring the electron affinity into an acceptable range. One conceivable escape from this dilemma is the use of stable hydrocarbon free radicals such as BDPA (α,γ -bis(diphenylene- β -phenylallyl)), which achieve a relatively high electron affinity (and low ionization potential) by virtue of a half-filled molecular orbital [75].

The degree to which an added electron or hole is delocalized over a CTM must affect the electron transfer matrix elements (and perhaps their dependence on intermolecular separation) and, presumably, the mobility. All other things being equal, in a given host polymer, it is also possible that the distribution of site energies is narrower for a CTM with a more highly delocalized charge distribution. The host environment presumably varies on the molecular distance [\AA] scale, and the site energy is determined by some sort of average over contributions of the various environments to which the charge distribution is exposed. The more extended the charge distribution, the more averaging may occur, and the narrower the resulting distribution of (averaged) site energies. This factor may be responsible for apparent differences in the nondipolar (van der Waals) contribution to disorder between CTMs of different chemical classes. Attempts at correlating mobility with the molecular orbital structure or degree of delocalization of the charge carrier within a CTM can be found in the literature [46b,e, 76].

Solubility in a host polymer (and a suitable coating solvent) is an important practical parameter for CTMs in general, and especially for electron-transporting materials with planar structures and highly polar substituents (features that tend to make a compound insoluble). In addition, electron mobilities tend to be relatively low, so that acceptable values can be achieved only with high concentrations of CTMs. Solubility can be enhanced by mixing CTMs with nearly identical ionization potentials or electron affinities [55j], by reducing the molecular symmetry using asymmetric substituents, by use of bulky solubilizing groups, or by connecting two or more charge-transporting moieties in a noncoplanar or flexible manner. This is the reason for asymmetric aryl groups in PTS [77a], the branched alkyl groups in NTDI [77b], the *t*-butyl group in DCAQ (2-*t*-butyl-9,10-*N,N'*-dicyanoanthraquinonedimine), and the "dimeric" structure of TAPC (Scheme 2). An additional advantage of bulky CTMs is that they tend to have relatively high glass transition temperatures

(T_g) by themselves, and, therefore, the necessary high concentrations in the host polymer may be achieved without reducing the composite T_g unacceptably. A disadvantage of bulky substituents is that they do not contribute to charge transport but do add to the molecular mass, thereby increasing the solubility requirements (on a weight basis) for given level of performance. These tradeoffs illustrate the “practical” considerations that influence the development of new charge-transporting materials at least as much as the “theoretical” considerations that we have discussed.

References are provided for additional extensive reviews featuring various viewpoints [3q, 14a, 59b, 77c].

2.7 Concluding Remarks

Organic photoreceptor technology is a major component of the multibillion dollar international business based on electrophotographic copiers and printers. From the original Xerox black-and-white copier, the business now encompasses products from desktop copiers and printers to high-speed commercial machines for on-demand printing applications. Today, color electrophotography is the area of greatest growth, from large and expensive high-speed color printers to relatively low-cost desktop devices for home and small office use. Most of these machines utilize organic photoreceptors as their photosensitive element. For these many applications, photoreceptors come in a variety of formulations coated on drum or polymer substrates. Each photoreceptor must have a manufacturing cost structure, and must provide the image quality required of the product, as determined by business analysis. Thus, the sensitometric and the physical characteristics of the photoreceptor must not degrade to the point that image quality suffers, over the product lifetime. Of course, the requirements for a small home or office printer are very different from those of a commercial printer. In a low-volume home or office machine the photoreceptor lifetime is often coupled with the toner capacity of a replaceable cartridge. When toner is depleted the entire assembly is replaced. Typically, the photoreceptor drum actually has remaining life, and the refinishing of used photoreceptor drums for resale has become a significant business. The situation is different in higher-volume electrophotographic devices. In these machines, replacement of the photoreceptor drum or belt is typically carried out by a highly trained service person. Degraded image quality results in a service call that requires diagnosis and repair. In newer models machines may be linked via computer to a service center for remote diagnosis. Because the photoreceptor element is central to the electrophotographic process it may become damaged in many different ways. Surface scratches, buildup of toner/paper deposits, and surface wear are common reasons for photoreceptor replacement. In these machines there is usually an advantage in having the photoreceptor last as long as possible. This means machine designs that prevent the accidental introduction of paper clips and staples, and component design for efficient photoreceptor cleaning without damage or excessive wear. In today's high-speed machines the organic photoreceptor elements typically last for

hundreds of thousands of imaging cycles. Thus, the electron transfer chemistry involved in each imaging cycle—corona charging, photoinduced charge generation, and field-driven charge transport—are repeated hundreds of thousands of times during the photoreceptor lifetime without substantial changes in their efficiency. This triumph of chemistry and physics is the product of many years of scientific study and technological development. Those fundamentals, which are the basis of organic photoreceptors, are now being applied to new areas such as organic light-emitting diodes, and organic photorefractive materials. Thus, the science and technology are moving together into new areas that will be the basis of the technologies of tomorrow.

3 Photorefractive Materials

David P. West and Mark D. Rahn

3.1 The Photorefractive Effect in Crystals and Amorphous Organic Media

3.1.1 Scenarios of Potential Applications

This chapter describes materials in which optical generation of mobile charges, followed by charge movement, leads to a change in refraction within a material. Photorefraction is an unusual optical phenomenon in some respects. Photorefractive materials react to the total fluence (the product of the exposure time and the intensity) of light incident upon them, not just the intensity, with the result that even very weak light may be used to control an optical system. The altered refraction is not local, it is shifted slightly in space away from the optical pattern that causes it with the result that the material can transfer energy from one light wave to another. The optical control of the material is completely reversible optically, so that the materials may be re-used as new. It is useful to consider the use of photorefractive materials in holography in order to describe the phenomenon. Many, but not all, of the applications that have been proposed for such materials depend on holography within the bulk of the material.

Many people are familiar with the idea of the hologram. The most common form of hologram is now mass-produced, creating a three-dimensional image that changes in appearance as the viewing angle is changed, and features on a credit card as an impediment to fraud. The ability for holograms to appear dramatically different at different viewing angles is an indication that much more information can be contained in this form than in a simple, two-dimensional image such as a photograph. Holograms are used commonly to provide a three-dimensional representation of an object; however, the images viewed from different angles need not be connected in any way (Figure 1). The hologram must be rotated or the viewing angle must be changed in order to see the different perspectives that are possible. It is this angle selectivity, this ability to isolate a particular image by the angle at which the light is observed, that leads to the proposal to store information with an ultrahigh density

Figure 1. A credit card is protected against fraud, using a simple hologram. Different images may be seen in the hologram from different viewing angles, illustrating the high information capacity of the hologram.

by writing many different holograms at different angles within the same volume of material. The hologram on a credit card is a permanent recording. An information storage system would be most useful if the information within it could be erased after use and then the storage medium could be re-used, in the same way as computer memory is re-used. Photorefractive materials offer this possibility.

The electronic signal amplifier is a common device, used to increase the power in electronic audio signals in a radio or a CD player, for example. An optical amplifier may be constructed using a population inversion within a laser gain medium. But can we amplify a beam that contains an image, to make the image brighter (Figure 2)? Using a photorefractive material we can construct a hologram by overlapping the image beam with an intense, uniform beam. The hologram that is created within a photorefractive material is shifted in phase relative to the optical interference pattern that creates it and allows coupling of light energy from one beam into the other, making such an image beam amplifier possible.

There are other applications of photorefractive materials that have been investigated, including associative optical memories that identify a clear image from a corrupted input [1], novelty filters to detect only changing features in an image [2], and neural networking in analogy with the human brain [3].

3.1.2 An Overview of the Sequence of Processes Leading to Photorefractivity

The trigger for photorefractive response is the exposure of the medium to an optical irradiation with a nonuniform intensity pattern. In practice, this usually means that two or more optical beams from the same source must overlap within the medium.

Figure 2. Amplifying a beam containing an image. Using a photorefractive material, the energy from a poor-quality, uniform pump beam can be coupled into the high-quality, weak beam containing an image. The beam is amplified and the image is retained.

If the two beams have a well-defined phase relationship, they will interfere to produce regions of darkness as well as regions of bright illumination. It is this coherent interference that has been used for over half a century to produce holograms in thick photographic emulsions such as silver halides.

In a photorefractive material the presence of light will lead to photoinduced electron transfer, which creates a charged ion together with a free charge carrier of opposite polarity. In the majority of amorphous organic photorefractive materials, a mobile hole is generated together with an immobile anion. The process of mobile charge generation after the absorption of a photon is generally assumed to be very fast ($\tau < 10^{-9}$ s) in comparison with the subsequent phenomena involved in photorefractive response. Typically the free hole population becomes saturated quickly because the lifetime of holes is short (although an estimate for amorphous organic media could be as long as $\tau_h \sim 10^{-4}$ s). During subsequent processes the rate of optical generation of carriers will be equaled by the rate at which they recombine with the immobile anion distribution.

In most cases an external electric field is applied across the material with the result that the mobile carrier distribution will experience drift in the field toward a new position. Even in the absence of an applied field, the nonuniform distribution of the mobile charge carriers created will lead to their relocation due to diffusion. Although the free carriers are generated where the optical intensity is high, their recombination with counterions (in the case of hole transport these are anions) may occur anywhere in the medium. This includes recombination where the intensity is low, resulting in the separation of the charge distributions. Subsequent optical excitation is unlikely in these darker regions. We know that the counterions exist in

dark regions because without them, holes would recombine only at sites of anions generated optically. The final state would then be indistinguishable from the initial state and no photorefraction would be observed.

Then, how is it that anions can exist in the darker regions, able to capture the mobile holes? Each mobile hole that is generated leaves behind an acceptor molecule that becomes charged negatively. The population of mobile holes saturates quickly in response to optical excitation, in a time equal to the mobile hole recombination lifetime. In order that charge redistribution may take place, the anion distribution must have a number density greater than that of the saturated mobile hole population. In these circumstances the immobile anion sites have a lifetime considerably longer than that for the mobile holes. The anion number density must have been large prior to optical irradiation. To preserve the electrical neutrality of the bulk material it is necessary that a similarly large and stable, immobile, cationic site density also exists. It is the presence of these immobile and passive charged sites of the same polarity as the mobile holes which makes it possible to have a large and steady population of immobile anions without a physically improbable high electric potential in the bulk of the material. For this reason, the immobile cations are sometimes referred to as compensators. The standard model of photorefraction assumes that the saturated population of mobile carriers is at least an order of magnitude lower in number density than the compensator density. The immobile cations and anions are distributed throughout the material, even in the dark regions, and electrical near-neutrality is preserved (Figure 3). In most cases of organic, glassy, photorefractive materials such as polymers, the matrix is a donor (hole) transport material. The anions are formed by the addition of sensitizer molecules, which have a higher oxidation potential and thus act as electron acceptors.

Recombination of the mobile charges in dark regions is not necessary for the photorefractive effect to be observed, but it is beneficial. If the mobile charges were to be removed completely, or redistributed uniformly with no dependence on the intensity pattern applied, then an immobile pattern of counterions would still be

Figure 3. Random distributions of ionized sensitizer anions and immobile cations coexist, trapped so that the recombination time is long. The smaller population density of mobile holes can be trapped by the anions anywhere within the medium.

Figure 4. The photorefractive effect with and without trapping. Top: the intensity pattern on the material. Middle: \circ , anion density; $+$, cation density; \times , ideal distribution of trapping of mobile holes. Bottom: comparison of the net charge distribution in the ideal case (no. of cations – no. of anions + no. of trapped holes, \times) with the corresponding space charge field in the absence of any trapping or recombination (no. of trapped holes = 0), (—).

created (Figure 4). The photorefractive effect is stronger when the mobile charges are subject to recombination. The term *trapping* is often used in photorefractive materials literature, and in most cases this refers to carrier recombination.

The initial sensitizer anion presence makes recombination of mobile holes possible in the dark regions. Which are the compensator sites? Here, there exist different explanations. One possibility is that some of the electro-optic dye molecules present in photorefractive composites to provide refractive index change may become charged positively. An alternative theory in the case of amorphous materials is that the amorphous disorder leads to defect sites forming local potential minima at which positive charge may be immobilized (Figure 5).

The mobile charge distribution becomes displaced relative to the static counterion distribution. This leads to localized regions with a nonzero net charge density, whilst the material remains close to neutral as a whole. Gauss' law of electrostatics

Figure 5. The amorphous structure of an organic matrix leads to a Gaussian density of states for the HOMO of the donor transport matrix. Some of the donors will have a relatively small oxidation potential (in the shaded region) and these sites are likely to experience a potential barrier inhibiting charge hopping to adjacent sites of higher oxidation potential. A hole may in this way become an immobilized cation.

dictates that the electric field must diverge from regions where there is a net charge density. Taking a simple example, if holes are created in a bright region and captured in a dark region, then the equilibrium anion densities will be highest in bright regions (net negative charge) and lowest in dark regions (net positive charge). The electric field is thus maximal where the intensity pattern is changing most rapidly, between the bright and dark regions (Figure 6), and is directed from dark region to bright region. In the simple case of a sinusoidal intensity pattern, the phase of the electric field profile is shifted relative to the intensity pattern by up to $\pi/2$ radians.

The difference between the locations of the mobile carrier generation and carrier recombination processes will build up a pattern of anions. A steady state of equilibrium will be reached in which the net distribution of charge no longer changes with time. At this point the electric field due to the relocation of mobile charge (the space charge field) has become strong enough to counteract the applied field in most cases of amorphous photorefractives (Figure 7). More generally the space charge field reaches a steady state for one of two possible reasons. Either the effect of the space charge field on the hole distribution becomes equal and opposite to the combined effects of diffusion and drift in the applied field, or all the available anion sites become filled.

Figure 6. The photorefractive effect. Top: in an idealized hole transport material, the net charge density is π radians out of phase with the intensity pattern. Middle: the electric field, E , due to this net charge density, ρ , is given by Gauss' law, $\partial E / \partial x = \rho / \epsilon$, and is shifted in phase by $\pi/2$ radians relative to the charge density distribution. Bottom: the refractive index will then follow the phase of the electric field. In real materials the charge distribution is not always π radians out of phase relative to the intensity pattern, as competition between drift and diffusion currents leads to a reduced phase shift. The refractive index contrast might therefore be shifted by only $\pi/10$ radians relative to the intensity pattern in some polymers.

An important aspect of the photorefractive effect is that the optical response of the material is nonlocal. In Figure 7, the position of the space charge field is displaced to the right of the initial excitation, in the direction of the applied electric field. In the case of a sinusoidal intensity pattern the phase shift between the optical excitation of charges and the electric field their movement produces is a parameter characteristic of a photorefractive material. It depends on the balance between the processes of drift and diffusion of mobile charges and on the number density of sites able to capture the mobile charges.

The electro-optic effect leads to the modification of the refractive index of a suitable material when an electric field is applied (Figure 8). The electro-optic effect must be present in a photorefractive material, so that the space charge electric field pattern due the relocated charges will lead to a patterned refractive index in the material: this is a hologram.

Just as a nonuniform intensity distribution was the trigger for the creation of a

Figure 7. Diffusion and drift of mobile holes. Top: the three curves show three instants in the process of drift and diffusion, equally spaced in time. —, A Gaussian distribution of mobile holes is created (with a corresponding distribution of photogenerated immobile anions). - - -, An applied field leads to drift of the holes to the right whilst the anions remain static, and as the holes drift, diffusion spreads out the hole distribution to twice its original width. · · ·, Later, the distribution has moved twice as far to the right and the diffusion has broadened the distribution to $2\sqrt{2}$ times the original width. (Hole recombination and space charge field effects have been ignored.) Middle: net charge distribution in space (no. of holes – no. of photogenerated anions) corresponding to each of the three instants. Bottom: electric field due to the space charge distribution corresponding to each of the three instants. The space charge field is acting to the left, opposite to the applied field. Eventually a steady state may be reached where the space charge field negates the effect of the applied field on the mobile holes.

hologram, so a uniform intensity distribution (such as from a single beam) can be used to distribute the mobile charge carriers uniformly. This is how a hologram in a photorefractive material can be erased.

3.1.3 A Historical Perspective

Earlier work on photorefractive materials was centered on the discovery of the properties of the phenomenon in optical crystals, most notably lithium niobate, strontium barium niobate, and barium tantalate. Both the mathematics of the theory of photorefractive materials outlined above and its application to these materials and

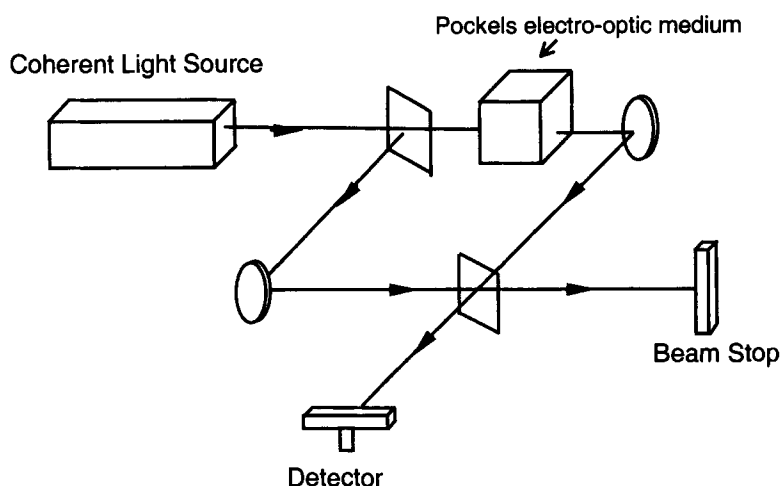

Figure 8. The Pockels effect leads to a change in the refractive index of an electro-optic material due to the application of a static electric field. This can be used to build a Mach-Zehnder intensity modulator, for example, which will have an optical transmission dependent on the electric field applied to the Pockels material.

other crystals are reviewed thoroughly in [4]. Photoexcitation produces mobile electrons in these crystals and these are trapped and re-excited in the optical field until they have moved away from the light. The electrons originate at defect and impurity points in the crystal such as Fe atoms. They may be trapped at other Fe atoms (Figure 9). The motion of the electrons is determined by a parameter called the mobility, which is well defined. (It is possible for a wave of electron density to travel through a crystal and remain largely intact.) The electric field that is produced by the modified electron density distribution will lead to a change in the refractive index because these crystals are electro-optic. The Pockels electro-optic effect is an instantaneous material response to an electric field, which leads to a change in refractive index that is proportional to the static electric field strength. The main issue for photorefractive crystal research from a materials perspective has been the difficulty in controlling the impurity concentrations within the crystal boules to an adequate degree such that the properties of crystals from different sources may be comparable.

More recently the promising range of applications for photorefractive materials has motivated the rapid development of amorphous, organic materials with a strong photorefractive response [5]. Here the chemical composition of the materials may be varied with relative ease and the opportunity to compare materials from different sources should exist. The various processes necessary for photorefraction may be obtained by a single material, or many different molecular species may be mixed in a composite to provide the range of properties needed. These amorphous materials do not have a well-defined mobility for the photogenerated holes that

Figure 9. Conventional model of photorefraction in crystals; iron impurity forms defect states of variable valence within the forbidden band gap of a lithium niobate crystal. Optical excitation of the divalent state leads to creation of a mobile electron in the conduction band. This is able to move and recombines with a trivalent iron impurity at another location which becomes divalent. The displacement of charge leads to an electric field and the Pockels electro-optic effect leads to local modification of the refractive index.

move through the medium. A wave of charge density will spread out as it travels through them, as the dwell time between hops depends on the varying microscopic environment. The electric field produces a change in the refractive index, often by rotating individual dye molecules which are anisotropic. There are many possibilities for new composites that are as yet untried. A photorefractive polymer composite was only first reported in 1991 [6]. The field is, as yet, immature, with much left to learn of the distinct physics and materials engineering of these new materials.

3.2 Electron Transfer in Amorphous Organic Photorefractive Media

The field of photorefractivity in organic polymers and glasses has been in existence for less than a decade. The understanding of charge generation in these materials (which are often composites) is not yet mature, and the behavior of some of the more common constituents is understood better. Much of the literature on photorefractivity describes free carrier generation quantum efficiency measurements only briefly, before a more detailed discussion of other factors such as mobility and electro-optic response. Some of the relevant information pertinent to free carrier generation in these materials is presented here, to be followed by a review of this aspect of the amorphous photorefractives literature.

3.2.1 Optical Generation of Bound Pairs

Free charge is generated indirectly in response to light within a typical photosensitive organic material. The initial optical excitation of the material will lead firstly to electron density transfer. The electric potential that binds together the two regions of opposite charge must then be overcome in order to create free charge. For many free charges to be created within the bulk of a material, both optically induced electron transfer and the subsequent dissociation of the charges must be efficient processes.

When a photon is absorbed, an excited state may be created in which a hot electron is created, along with a localized hole. The electron thermalizes at some distance away from the hole, leading to a charge transfer state. The electron and hole of the charge transfer state are not free charge carriers. The opposite charges associated with the two sites will lead to an electric attraction between them and a significant degree of geminate recombination will occur. For free charge carriers to be generated a proportion of the electron-hole pairs will have to dissociate so that the distance between them is sufficient to overcome the electric attraction.

In the conventional analysis after Onsager [7], the probability of forming such a bound charge pair and the distance between the two charges generated are material parameters independent of temperature or electric field, but inversely proportional to the photon energy of the excitation wave. An efficient pair generation process will be associated with longer excitation wavelengths and greater separations between the hole and the electron that are generated. In the case of molecular doped materials an increase in the concentration of the dopant will increase the thermalization distance and the primary yield of charge transfer states.

The Onsager formalism has its shortcomings: it assumes that direct thermalization of the hot electron takes place and this implies that there should be an excitation wavelength dependence for the primary yield of charge transfer states. In real organic materials any such wavelength dependence is weak and it is possible that there is some form of internal conversion process or intermediate that removes the expected spectral dependency [8]. This point is rarely made in the interpretation of experimental results, as it requires additional, unknown parameters to be fixed during the analysis of data.

The oscillator strength of the charge transfer absorption will depend on the overlap integral for the transition involved. Both the spatial arrangement and energetic relationship between the donor site and the acceptor site will influence this. A charge transfer absorption band in an absorption spectrum is usually a broad peak across the visible or near-infrared. In contrast to this, stronger and more defined peaks are observed at shorter visible and near-ultraviolet wavelengths which correspond to more localized excitations associated with a specific donor or acceptor moiety within a molecule. Highly localized molecular excitons able to transfer between molecules may be created at these shorter wavelengths (Frenkel excitons).

The electric attraction between the photogenerated electron-and-hole pair must be overcome for free charge to be generated. The distance between the two charges must be increased until each charge is free from the electric field of the other. Within a

uniform homogeneous material, this may be achieved efficiently under the influence of an electric field drawing the opposite charges in opposite directions. For example, in pure TiO-phthalocyanine (TiOPc), carrier generation is observed to take place within the bulk of the TiOPc material. A molecule in an excited state will accept an electron from a neighboring molecule in an interaction which is dependent on an applied electric field, and a bound pair is created.

The mobility of holes is greater typically than the mobility of electrons in organic media [9]. Organic donor molecules will often form an efficient hole transport medium and a suitable photosensitizer for this must act ultimately as an electron acceptor after illumination. When a sensitizer such as TiOPc is used either in particle form or in layers within a hole-transporting material, then a reaction may occur between a photogenerated bound pair in the TiOPc and the surrounding donor matrix at the surface of the TiOPc. The hole of the bound pair may be filled by an exothermic electron transfer from the adjacent donors. The result is a bound electron-hole pair in which the positive charge is within a hole transport medium whilst the negative charge is still within the photosensitizer. According to the (classical) Marcus theory [10] this forward reaction will be associated with the release of a characteristic reorganization energy typically of 0.05–0.2 eV. The process is efficient if the difference in the ionization potentials of the photosensitizer and the hole transport molecule is approximately equal to this reorganization energy.

In practical organic devices for the photogeneration of charge, a heterostructure is often used in which there is a second material with a different energy level structure. There may be a catalytic effect at an interface between a photosensitive dopant layer and a hole transport layer. In this, the difference between the ionization potentials on either side of the interface creates an energy gradient, lowering the activation energy required for the generation of an electron-hole pair. The donor cation and the acceptor anion have a lower collective energy than their neutral ancestors and this helps to stabilize the charge transfer. In sensitizers based on azo dyes, an exciton-driven reaction creates two charged ions from neutral molecules by the movement of a charge. The products are bound together more tightly than the reagents and the process is efficient if it is sufficiently exothermic (relative to the reorganization energy) [11]. Laminar devices in which hole-transporting layers are alternated with photosensitive layers have formed highly efficient photoreceptor systems. The primary yield of bound pairs from the extrinsic (interface) mechanism is found experimentally (by photoluminescence quenching measurements [12]) to be independent of applied electric field. Without the laminar heterostructure and the consequent surface enhancement, a single-layer device exhibits strong electric field dependence for the yield of bound electron-hole pairs [9].

Experiments using a two-layer heterostructure in which the photocurrent action spectra are observed both for front and rear (sympatric and antipatric) illumination of the interface between a photosensitizer and a hole transport layer have shown that the surface enhancement of bound pair generation is due to a layer typically 300–500 nm thick [13]. Within this distance of the interface, excitons generated by the optical absorption may diffuse toward the interface and initiate bound pair generation. The importance of these excitons for a specific photoreceptor can be iden-

tified from electroabsorption measurements. Frenkel exciton excitation is identified where the electroabsorption spectrum matches the derivative of the linear absorption spectrum with respect to the photon energy [14].

3.2.2 Dissociation of Bound Pairs into Free Charges

The process of bound pair generation is independent of electric field in laminated azo dye-sensitized devices. In contrast to this, the dissociation of the bound pairs depends strongly on an applied electric field. Consequently, in low electric fields the free charge generation process is limited by dissociation whilst under the influence of strong electric fields the process of generation of bound pairs is the factor limiting the efficiency of free charge photogeneration.

The efficiency of generation of free charge can be measured experimentally using xerographic discharge or time-of-flight techniques, discussed later. It is conventional to regard the charge photogeneration efficiency as the product of the efficiency of electron transfer to create bound pairs and the efficiency of dissociation to create free charges. The dissociation efficiency must be deduced from the ratio of the quantum efficiency of charge generation to the efficiency of electron transfer (from photoluminescence quenching).

In azo-dye-based laminar photoreceptor systems, neither the dissociation efficiency nor the primary yield of bound pairs is dependent on excitation wavelength [11–13]. There is a strong positive linear correlation between the dissociation efficiency and the peak value of the dipole moment associated with the transition between the ground and first excited states in the azo photosensitizer (obtained from electroabsorption data) [14]. It is likely that in these systems the efficiency of dissociation is constrained by the electron transport process away from the interface into the bulk of the sensitizer material, because transport of holes through the donor matrix is much more rapid.

3.2.3 Choice of Photosensitizer

The photosensitizer within a molecular doped material exhibiting hole transport must act as an acceptor. Common hole transport materials are based on triphenylamines, aromatic amines such as carbazoles, fluorenones, and benzenes. Common acceptors include dyes (such as malachite green), trinitrofluorenone, and the fullerenes C_{60} and C_{70} . Of these, the fullerenes are unique in their properties [15]. The thermalization distance for hot electrons generated by fullerene sensitization (0.65 nm) is smaller than the size of the fullerene itself (0.7 nm) in experiments using polyimides as electron acceptors with pendant triphenylamine donors. For very low concentrations of doping (0.07 mol% C_{60}) under high applied fields the absorption cross-section for fullerene is 300 times greater than that for intrinsic or dye-sensitized photogeneration. The dipole strength of the fullerene-sensitized photogeneration transition appears to be as great as 26 D, greater by a factor 17 than the dipole for the intrinsic or dye-sensitized processes. It is not possible, however, to project this

high performance of C₆₀ to higher concentrations within photorefractive composites. Fullerene performance falls at higher concentrations. At concentrations of C₆₀ above 1 wt.% in a typical photorefractive composite black carbon deposits are found to separate out within the composite during the sample fabrication process.

Within inorganic photorefractive crystals the optical generation of carriers is associated usually with the oxidation of defect and impurity states within the optical band gap of the crystal, such as iron impurity within lithium niobate crystals, as in Figure 9.

Much of the initial work on photorefractive polymers and organic glasses was based on this prior understanding of the analogous crystal process. Host matrices have been adopted which, when pure, are transparent to visible light because there is a wide optical band gap between the HOMO and LUMO levels which corresponds typically to excitation in the near-ultraviolet region of the spectrum. The absence of a crystal field makes the addition of an electro-optic material necessary for photorefraction to be observed. The optical nonlinearity is obtained normally from a significant concentration of chromophores, so-called because they exhibit a charge transfer resonance at blue or green optical wavelengths which gives them a distinct color. These chromophores have an optical band gap that is smaller than that of the host matrix. Sensitizer material is added at a low concentration, to perform a role which is analogous to the defect density in crystals. The reduction of the sensitizer dopant leads to photogeneration of mobile holes within the oxidized donor transport matrix. A charge photogeneration resonance is required that is further spectrally toward the red than the long-wavelength tail of the chromophore resonance, as in Figure 10. This is normally obtained by using a sensitizer which forms a charge transfer complex with the donor transport matrix.

The host matrix itself is a charge transport system in many of the high-performance, glassy photorefractive materials: the most common matrix for photorefractive composites is poly(*N*-vinylcarbazole), PVK. In some early materials, a dielectric host matrix was used into which a transparent donor charge transport agent such as *p*-diethylaminobenzaldehyde diphenylhydrazone, DEH, was doped [16, 17]. In the latter case, transparency at visible wavelengths is maintained if the HOMO level of the dopant is sufficiently close to the HOMO of the host dielectric matrix, so that a large electron energy band gap is preserved.

The intrinsic optical absorption of the host matrix and the nonlinear chromophores should be minimized at the operating wavelength. Such absorption may lead to undesired, photochromic, refractive index modulation that is in phase with the optical intensity pattern within the material. (Photochromism is a photoinduced change of molecular state which could lead to changes in refractive index and absorption coefficient.) The photochromic response will have a distorting effect on hologram formation and reduce the phase shift of the refractive index profile relative to the intensity pattern. The additional absorption acts parasitically to reduce the amplitude of the photorefractive response. The performance of photorefractive materials is optimized by selecting an optical wavelength for recording and readout for which there is sufficient absorption due to the presence of the charge generation sensitizer within the donor matrix. At the same wavelength the absorption due to the host matrix or the nonlinear chromophore alone should be low.

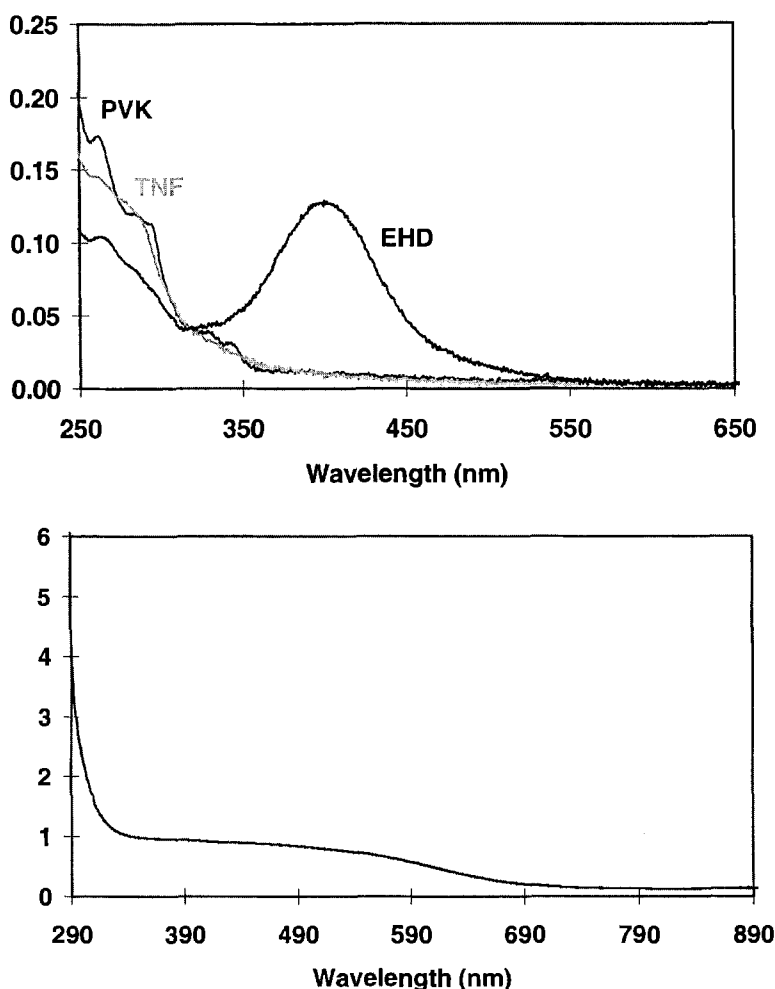

Figure 10. Top: liquid-phase absorbance spectrum of each component of a typical photorefractive polymer composite. Each component, *N*-vinylcarbazole (PVK), 2,4,7-trinitro-9-fluorenone (TNF), and typical chromophore (EHDNPB), is diluted in dichloromethane separately. (Absorption due to the solvent has been subtracted.) Bottom: the absorbance of light in a solid sample due to the charge transfer complexation between PVK and TNF. The sample was prepared from a 9:1 ratio of PVK/TNF. The extension of absorption to longer wavelengths is clear.

The energetic positions of the HOMOs of the nonlinear chromophores (and the charge transport agents, if used) are obtained approximately (relative to the host matrix) using cyclic voltammetry in solution. The solvation energy and polarization energy may lead to discrepancies between the solution-based experimental results and the actual energy levels within a solid solution or polymeric material. As an acceptor, the sensitizer will have an oxidation energy greater than the charge-

Figure 11. Possible relative positions of the energy levels in a typical guest–host photorefractive polymer composite containing PVK, TNF, and an azo-chromophore. A possible sequence of events leading to mobile charge generation is also included.

transporting donor network. The oxidation energy of the nonlinear chromophores is likely to be lower than that of the sensitizer and it is possible that the chromophores may be oxidized more readily than the donor network. The chromophores are present at a significant concentration and thus they may affect either the charge generation or the charge transport process, as in Figure 11.

Most of the potential applications for photorefractive materials are based on the creation of holograms within the bulk of the material. The material is intended generally to be homogeneous under uniform illumination, and of high optical quality, and the optical scatter of light should be minimized. For this reason, molecular doping of sensitizer is used typically at a low (~ 1 wt.%) concentration to produce weak photoabsorption at the operating wavelength, which is typically in the region 650–750 nm. The primary quantum yield of bound pairs in organic, glassy, photorefractive materials is as high as 40 %, although relatively few reports have been made [17, 18]. The dissociation of photogenerated bound pairs is expected to be strongly field-dependent because heterostructures that introduce an interface between a bulk photosensitizer layer and a hole-transporting layer are not

Figure 12. Charge sensitizers used in organic photorefractive materials.

used. An electric field of up to $100 \text{ V } \mu\text{m}^{-1}$ will lead to a quantum efficiency of mobile carrier photogeneration that is only a few percent.

3.2.4 Specific Material Systems

The most common format for a glassy organic photorefractive material is to use a charge-transporting polymer or glass such as PVK, polysilanes (PS), polysiloxanes (PSX), triphenylamine (TPA), or the starburst molecule and its derivatives. Earlier work also included the passive matrices poly(methyl methacrylate) (PMMA) and polycarbonate, into which a charge transport agent, such as DEH, was added. To complement the hole transport material, a specific charge sensitizer is also added; Figure 12 shows the chemical structures of some of the charge sensitizers that have been studied.

In the case of PVK, a charge transfer complex may be formed by the addition of a small amount of 2,4,7-trinitro-9-fluorenone (TNF). The PVK–TNF system has been studied widely in xerography and as a two-component material it is well understood [19]. It also has the additional advantage of a particularly low photoconductivity in the absence of light. Photoconduction due to the complex is efficient across the visible region of the spectrum, with the excited state exhibiting 80 % electron transfer from a carbazole unit of the PVK to an adjacent TNF unit. The dissociation of holes occurs in the two-component system by hole transfer to

neighboring carbazole units, away from the immobile TNF anion. It is unclear at present to what extent the presence of the nonlinear chromophores at up to 55 wt.% concentration affects this process. Charge transfer complexation between the sensitizer and the chromophores is possible and this may reduce the free charge photogeneration efficiency. Trinitrofluorenone dimalenitrile (TNFDM) is a derivative of TNF with an increased electronegativity that leads to a charge transfer complex with carbazole units of PVK. The complex between PVK and TNFDM has a spectrum of sensitivity for charge photogeneration which extends further into the infrared than the corresponding complex between PVK and TNF. At the longer wavelengths, chromophore absorption and optical loss are reduced.

As might have been anticipated, C_{60} has been found to be very effective as an acceptor-sensitizer for homogeneous photorefractive polymers. The absorption associated with the C_{60} molecule in isolation is unusually low, which minimizes parasitic optical losses and inhibits photochromic grating formation. The efficiency of photogeneration of free carriers is relatively high, despite the absence of bulk photosensitizer layers; this may be linked to the small thermalization radius associated in the Onsager picture with C_{60} and the correspondingly high efficiency of dissociation. Under strong electric fields of up to $100 \text{ V } \mu\text{m}^{-1}$ the quantum efficiency of photogeneration of free carriers from photons absorbed has been found to remain nearly constant in a photorefractive composite as the intensity of illumination is increased by three orders of magnitude, up to 1 W cm^{-2} . The photoconduction of the composites is near-linear with intensity ($\sigma \propto I^{0.85}$ to $I^{0.9}$) [20].

The efficiency of charge generation within the photorefractive material is one of the key parameters governing the rate of response of the material. A simple model based on instantaneous charge transport and trapping may be used to calculate an upper limit to the rate at which a photorefractive grating is recorded optically, due to the limited rate of free charge photogeneration. The rate of growth of the electric space charge field, E_{sc} , is constrained due to the need for charge generation according to Eq. (1),

$$\frac{\partial E_{sc}}{\partial t} \leq \frac{\phi \alpha I}{\hbar \omega} \frac{e \Lambda}{2 \pi \epsilon_s} \quad (1)$$

where ϕ is the product of the primary yield of bound pairs and their dissociation efficiency, α is the absorption coefficient, I is the intensity contrast, e is the electronic charge, Λ is the period of the intensity pattern, $\hbar \omega$ is the photon energy, and ϵ_s is the static dielectric constant. This model idealizes the mobility of charge and the characteristic transport length of the free charge carriers. It is obtained from the standard model of photorefractive under the assumptions of a long hole lifetime and a high mobility.

The effect of a limited mobility of holes in the material may be accounted for in Eq. (1) by using a parameter called the mobility field, E_m , which is the electric field necessary for a hole to drift 1 radian across a sinusoidal intensity pattern in one hole recombination lifetime. The assumptions of long lifetime and high mobility make the mobility field small in comparison with the projection of the poling field along

the diffraction grating vector, $E_0 = E_{\text{pol}} \sin \theta_{\text{int}}$: the correction factor to the rate limit in Eq. (1) for a mobility field which is not negligible is $|E_0(E_m + jE_0)^{-1}|$.

We can estimate the highest rate of growth of the space charge field in various composites, from data published for the growth of grating diffraction efficiency. In the literature, time constants are most often quoted for the growth of the refractive index contrast, Δn , of a grating. Most of the efficient photorefractive materials are close to the glass transition temperature at room temperature. The chromophores typically have a significant electric dipole moment in their ground state and they change orientation slightly in an electric field. In one time constant of field formation, the field reaches 63 % of its maximum value, which is limited by the poling field projection, E_0 . The gradient of the rising exponential has a peak value around 50 % greater than the linear approximation from the origin to 63 % of saturation in one lifetime (Figure 13). Accordingly we estimate a peak value of observed field growth rate to be given by Eq. (2),

$$\left. \frac{\partial E_{\text{sc}}}{\partial t} \right|_{\text{max}} \approx 0.63(1.5) \frac{E_0}{\tau_{\text{fast}}} \quad (2)$$

where τ_{fast} is the fast time constant of index contrast growth quoted. Many of the amorphous photorefractive materials come close to the charge generation limit in their rate of holographic response, as shown in Table 1. The difference between the charge generation limit of Eq. (1) and the observed peak field growth rate calculated using Eq. (2) may indicate that in the experiments referred to in Table 1, the magnitude of the mobility field was close to that of the projection of the poling field. One caution in this analysis is that data for the quantum efficiency, ϕ , of generation of mobile holes due to incident photons of light are not reported in many papers describing photorefractive materials. Accordingly, the quantum efficiency must

be estimated in many cases; the efficiencies used in this comparison in Table 1 are stated.

A number of recent reports have described hologram recording on time scales of 1–10 ms, using a high optical intensity and uniform preillumination (see Table 2). There is not yet a clear consensus in the literature as to how the fast responses have been possible: several factors may be involved.

Table 2. Rate of response of “fast” amorphous photorefractive materials: a comparison of the experimental fast time constant of growth of contrast in refractive index in response to a nonuniform intensity pattern and the theoretical rate limit based on charge photogeneration rate.

In Table 2, the analysis of these fast results for hologram recording time has been adapted to take account of the fact that reorientation of the chromophores may not be possible on a time scale of milliseconds. This has two consequences. Firstly, the space charge field formation process depends on the static dielectric constant. In materials with significant chromophore reorientation at room temperature, the static dielectric constant is in the region of $20\epsilon_0$ (this is the value of dielectric constant that has been used in the preparation of Table 1). If the process of space charge field growth becomes faster than the reorientation process, the dielectric constant will drop close to the value at optical frequencies, in the region of $3\epsilon_0$. For a time less than the reorientation time for the chromophores in the photorefractive composites, the rate of space charge field formation in the charge generation limit is almost an order of magnitude enhanced.

Table 2 compares the holographic growth time constants reported for several fast materials with the "fast" charge generation limit to space charge field formation, valid when the reorientation of chromophores is slower than the initial rate of space charge field formation. The response rate calculated for many fast materials appears to have exceeded even the adapted charge photogeneration limit, which is not possible. This contradiction may be due to uncertainty in the quantum efficiency estimations used (which may not have been confirmed experimentally). A more systematic explanation may be that the space charge field is not reaching its *poling field limit* in these cases within the time scales described: the analysis used in Table 2 still assumes the space charge field reaches 63 % of its poling field limit within one time constant. In this case the amplitudes of the fast signals diffracted are likely to be small. It is not possible to confirm the amplitudes of diffraction from the papers published to date.

Uniform preillumination is discussed in the literature in two different time regimes. Fast diffraction response is obtained from materials which are illuminated uniformly and intensely for a few seconds before a second writing beam is used to pattern the intensity in the material and begin hologram formation. This maximizes the mobile hole density in the material at the time of hologram formation and helps to reach the charge generation limit of Eq. (1).

According to the literature, uniform and intense preillumination in an electric field for a period of hours has been introduced as a means of material modification. The extended preillumination has been demonstrated to increase the rate of response in transient photocurrent measurements, but to decrease the magnitude of the photoconductivity [27]. This is because the hole recombination lifetime is reduced due to an increased population of sensitizer anions. In the case of C_{60} as a sensitizer, the population density of the anion has been confirmed spectroscopically to rise as expected after extended preillumination. What is the effect of this on the rate of the hologram formation process? In typical materials the correlation between photoconductivity and hologram recording rate exists only under conditions of constant mobility \times lifetime product for the mobile holes. The exception to this is when the mobility is unusually low. Under the normal operating conditions of a typical amorphous photorefractive material, hole diffusion may be neglected relative to drift in the poling field and the space charge field is not normally limited by

the saturation of recombination sites. The preillumination over a period of hours will increase the anion density, increase the saturated electric field when all available recombination sites are filled, and consequently slow down the hologram recording process.

3.2.5 Fully Functional and Permanently Poled Materials

The requirement for high optical quality has encouraged the development of multipurpose molecules for photorefractive composites and also the synthesis of single-polymer, fully functional materials. In fully functional materials charge photogeneration, transport, and electro-optic response have been combined through the use of distinct monomer units or side-chain substitutions. These materials are less common in the literature, due primarily to the great synthetic effort that is needed for each modification to the materials. Two examples are presented in Figure 14. Of these, an interesting and contrasting case is of a fully functional polymer containing a ruthenium–ligand charge transfer complex for photogeneration of electrons [33]. The polymer backbone is a π -conjugated electron transport material and an electron is promoted to a mobile state when the Ru^{2+} ion is oxidized to the trivalent state. This material is in some respects very different from the majority of photorefractive polymers and glasses. The most notable difference is that electron transport occurs leading to recombination at cationic sites such as Ru^{3+} . The high phase shift of the photorefractive response suggests that there may be a low electron trap density. The quantum efficiency of 0.2 % for 690 nm wavelength illumination in a poling field of $95 \text{ V } \mu\text{m}^{-1}$ is not particularly high, however. The authors noted that an internal field of about $20 \text{ V } \mu\text{m}^{-1}$ was observed in the absence of an applied field in this material, due to permanent corona poling of the polymer above the glass transition at 130°C . Such a permanently poled polymer exhibits a photorefractive response without a poling field applied, but the response is slow—on the order of 700 s—and the refractive index contrast is not enhanced by the room-temperature reorientation of chromophores.

3.3 Charge Transport Processes in Amorphous Organic Media

Charge transport processes are essential to the operation of organic photorefractive materials. Positive and negative charge must move and separate to enable a space charge field to be established. There are several reports indicating that holes dominate charge transport in organic photorefractive materials [5]. Thus holes produced upon the excitation of a charge-generating molecule or charge transfer complex must be able to migrate from their point of origin and become separated from their corresponding sensitizer anions.

Figure 14. Examples of fully functional photorefractive polymers.

3.3.1 Transport in Disordered Media

Hole mobilities in glassy organic materials are often studied using the time-of-flight (TOF) technique (Figure 15). In this technique mobile charge generation is induced optically on one surface of a thin film of the material under study. Optical absorption must occur principally near one electrode. If the absorption is insufficient for this, then an extra charge generation layer with a high absorption is used. A short (usually nanoseconds) optical pulse is applied to photogenerate mobile charge and the time evolution of the photocurrent is measured. A typical signal is shown in Figure 16, where the position of the shoulder indicates the time taken for the charge packet to cross the device, after which the current decays. The transit time, t_{tr} , is

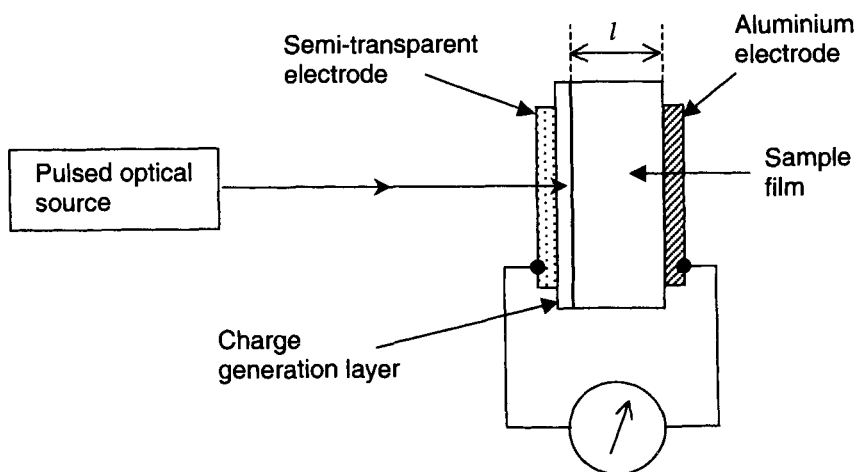

Figure 15. Experimental arrangement for time-of-flight measurements. One edge of a thin film ($\approx 1 \mu\text{m}$ total thickness) is optically excited and charge carriers are produced near the surface of the film. If the optical density of the film is insufficient to absorb the bulk of the irradiation in the first 10 % or so of the film, then a separate charge generation layer is used. A current is detected as the charges migrate across the film until all the photogenerated charge reaches the other electrode.

Figure 16. Transient photocurrent signal from a time-of-flight measurement of a photorefractive polymer composite containing 47.5 % electro-optic dye (EHDNPB), 1 % TNF with PVK polymer making up the remainder; 21 V was applied across the 100 nm polymer film and a 10 nm thick rhodamine 6G charge generation layer was used. The hole mobility in this material is thus $2.5 \times 10^{-6} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$.

related to the hole mobility by Eq. (3),

$$t_{\text{tr}} = \frac{l^2}{\mu V} \quad (3)$$

where l is the thickness of the film, V is the voltage applied across the sample and μ is the mobility of the primary charge carriers, usually holes in amorphous organic photorefractives.

All experimental data collected to date indicate that hole transport in most organic photorefractive materials is dispersive in nature, which is a characteristic of most glassy organic materials. In the regime of dispersive transport, charge carriers do not have a clearly defined mobility and the sheet of charge generated in the TOF experiment broadens as it drifts across the device (recall Figure 7). This is a consequence of holes dwelling for different periods of time at different individual sites within the material before hopping to their next dwell site. The dwell time distribution arises from many sources, including positional disorder (a distribution of the distances between individual hopping sites). The dwell time distribution can be described using the empirical distribution first reported by Scher and Montroll [34] (Eq. (4)),

$$\psi(t) \approx \text{constant} \times t^{-(1-\alpha)} \quad (4)$$

where α is the disorder parameter ($0 < \alpha < 1$) which governs the width of the dwell time distribution. This distribution implies a mobility dependence on the disorder parameter: $\mu \propto (l^2/V)^{1-1/\alpha}$. The analysis of Scher and Montroll is, however, incomplete, as it cannot explain the mobility dependence on temperature or applied electric field adequately.

The treatment by Bässler is more complete [9, 35]. This includes two mechanisms for a distribution of dwell times in glassy organic materials arising from positional and energetic disorder. For a hole to hop between hopping sites, the wavefunctions corresponding to each site must overlap. Figure 17 is an illustration of the theory using the example of hole hopping sites represented by square potential wells. It can be seen that a distribution in the distance between two wells will affect the dwell time. The difference between the depths of two wells will also affect the dwell time. In a unidirectional hole drift process, the dwell time will be longer if the next available site has a higher energy. Energetic disorder arises from fluctuations of the molecular energy levels in amorphous materials. This energetic disorder is brought about by variations in the van der Waals, ion-induced dipole, or ion-permanent dipole interactions between molecules at neighboring dwell sites and results in Eq. (5) for the hole mobility,

$$\mu(T, E) = \mu_0 \exp - \left(\frac{T_0}{T} \right)^2 \exp \left(\frac{E}{E_0} \right) \quad (5)$$

Figure 17. The effects of A) positional and B) energetic disorder on hole hopping. The separation between hopping sites affects the overlap between the wavefunctions of adjacent sites, and therefore the rate of tunneling between sites. The distribution of energies is assumed to have no effect when hopping to a site of lower energy, but the hopping rate to a site of increased energy is impeded by a Boltzmann factor $\exp[-\Delta E/kT]$.

where μ_0 is the mobility in a similar system lacking disorder, and T_0 and E_0 are material parameters which increase and decrease respectively with increasing width of the energy level distribution. The general conclusion of this theory is that increased energetic disorder effectively increases the width of the energy level distribution and reduces the apparent hole mobility. Experimentally it has been confirmed that an increase in the size of dipole moments within the polymer can increase ion-permanent dipole interactions and thus increase the width of the energy level distribution and yield significant reductions in mobility [36]. Increases in the average distance between hopping sites (by dilution with a nontransporting material, for

example) yield more modest mobility changes, typically by less than an order of magnitude.

3.3.2 Specific Examples of Hole Transport Materials for Organic Photorefractives

Figure 18 shows a selection of the hole-transporting organic materials that have been used to date as components in photorefractive composite materials. The hole transport process in these materials occurs via hopping between the aromatic moieties. Mobility data are given in Table 3. Most, but not all, of these materials are polymers. The polymer chains can be regarded as existing in a disordered, glassy state; thus hole hopping occurs simply between adjacent moieties, wherever they lie and not necessarily along discrete polymer chains. More recently fully functional glasses have been developed using low molecular weight molecules incorporating both electro-optic chromophore and hole transport moieties. These materials are not polymeric, but form glassy matrices that are likely to have similar hole-transporting properties.

Table 3 illustrates how the hole mobilities of a selection of relevant materials vary significantly from $10^{-3} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ in poly-(9,9'-dioctylfluorene-*co*-*N*-(4-butylphenyl)-diphenylamine) (TFB) through $1.5 \times 10^{-5} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ for a polysilane-based polymer to $2 \times 10^{-6} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ in a PVK-TNF complex. TFB is an interesting polymer as it combines hole-transporting fluorene groups with a conjugated polymer. This combination technique produces high-mobility polymers. Other polymers similar to TFB show no dispersion for hole transport because of a subtle canceling-out of positional and energetic disorder.

The addition of large quantities of TNF to PVK reduces the hole mobility by two orders of magnitude [19]. Table 3 indicates mobilities in pure hole-transporting materials rather than doped materials. The hole mobility obtained when these pure materials are incorporated into photorefractive composites also containing the associated nonlinear and charge generation components is almost always lower by anything between a small factor and many orders of magnitude, as shown in Table 4. Only in one material given here, consisting of the polysilane polymer and the dye Coumarin 153, was the hole mobility higher in the composite than in the pure hole transport material. This indicates the possibility of significant hole transport in the dye; thus it is misleading to assert that hole transport necessarily occurs in the recognized hole transport material within a composite (recall Figure 11).

Also shown in Table 4 is the hole transit time, calculated from the hole mobility for each photorefractive material, across a typical grating spacing that would occur in a photorefractive hologram. This time would be the response time for grating growth if all the other processes were fast, including charge generation and chromophore reorientation (see Sections 3.2 and 3.4). It can be seen that the mobility-limited response time is always much faster than the actual response time of the material. In fact, even if the lowest mobility is taken, the response time would not be much slower than that of the fastest material yet reported. It can be concluded, therefore, that the mobility is not a critical parameter for the optimization of organic photorefractives.

3.3.3 Pulsed Excitation and Charge Trapping

An alternative and seldom used technique for measuring hole mobility is the holographic time-of-flight technique [40]. Like time of flight, holographic time of flight (HTOF) measures the transit time of charge carriers across a known distance, but this time across a grating period ($\approx 3 \mu\text{m}$) within a hologram in the bulk of a thick film. This experiment utilizes a degenerate four-wave mixing experimental arrangement. Two coherent pulsed laser beams interfere within a sample to produce a sinusoidal intensity distribution in the bulk of the material. Assuming that excitation and charge separation processes occur quickly compared with charge transport across the intensity modulation period, overlapping sinusoidal distributions of mobile holes and corresponding stationary sensitizer anions are formed. As the mobile holes drift under the influence of an external poling field, they become separated from their sensitizer anions and a space charge field is generated. Traversing half a period of the intensity pattern, charge separation reaches a maximum along with the space charge field. After traversing one full period, holes again spatially coincide with their sensitizer anions and the space charge field reaches a minimum. In the absence of significant dispersion or recombination, the space charge field amplitude would oscillate as waves of hole density drift through the bulk of the material. If the material were electro-optic, the space charge field would produce a refractive index grating and the diffraction efficiency of a continuous probe beam would oscillate with the space charge field. A time of flight could be established from the oscillation period, yielding the transit time across a period of the hologram.

Figure 19. A typical HTOF signal from the photorefractive polymer composite PVK/0.1 wt.% TNF and 40 wt.% 4-(hexyloxy)nitrobenzene electro-optic chromophore, reproduced with permission from [42]. A clear peak is observed which represents the transit time of holes across half a grating period. Eventually a steady state is reached due to the spatial hole distribution being smeared out by dispersive transport and hole recombination.

Figure 19 shows the diffraction efficiency obtained from a photorefractive polymer in an HTOF experiment. A maximum diffraction is followed by a decay to a steady state, due to dispersive transport and charge recombination. In reorientational materials, the time constant for orientation must be either considerably longer or shorter than the transit time for an interpretable signal to be obtained. Even in the absence of reorientational effects, dispersive transport smears out the sinusoidal hole distribution into a uniform one during the drift process. Under these circumstances, no oscillation is observed and the space charge field is formed primarily via the stationary, sinusoidal distribution of sensitizer anions. The space charge field is therefore semipermanent, erased by uniform illumination under an applied electric field. Hole recombination occurs almost uniformly. The initial concentration of sensitizer anions is approximately equal to the photorefractive trap density.

3.4 An Overview of Amorphous Organic Photorefractives and Their Applications

3.4.1 The Electro-optic Response

In order for the space charge field to produce a refractive index modulation and hence a grating or a hologram within the organic photorefractive material, the

material has to show an electro-optic response. Like inorganic materials, organic photorefractives can yield a refractive index modulation via the Pockels effect. If the material is fully functional it will have a known nonlinear moiety attached covalently to provide an appreciable Pockels response. Alternatively, the material may be doped with a relatively high concentration of a nonlinear optical chromophore. Examples of chromophores used are shown in Figure 20. Additionally the material must be anisotropic, which generally means that the material must be electric-field-poled to provide some degree of alignment. Many organic photorefractive materials also possess an enhanced nonlinear response via reorientational birefringence. Reorientational birefringence occurs if the glass transition temperature of the material is below ambient and the dipolar chromophores can reorientate themselves in response to an applied electric field or a space charge field modulation. The low glass transition temperature is achieved by the addition of a suitable

Figure 20. A selection of chromophores used in guest-host organic photorefractive materials.

Figure 21. A selection of plasticizers used in organic photorefractive materials

plasticizer to the composite [44] (Figure 21), although in some cases simply adding a high concentration of a suitable electro-optic chromophore provides sufficient plasticization [45].

Molecular alignment distorts the index ellipsoid and rotates it to align along an electric field. An applied electric field thus causes the refractive index for an optical beam to change. An optical beam with an associated electric field E_{opt} directed along, or perpendicular to, the applied electric field E_{appl} will experience a refractive index change due to molecular alignment (neglecting the Pockels effect) according to Eqs. (6),

$$\begin{aligned}\Delta n(E_{\text{opt}} \parallel E_{\text{appl}})_B &\propto \frac{2}{3} A_2 \\ \Delta n(E_{\text{opt}} \perp E_{\text{appl}})_B &\propto -\frac{1}{3} A_2\end{aligned}\quad (6)$$

where the second-order coefficient, A_2 , is related to the average angle, θ , between

the optical axis of the chromophore and the electric field such that Eq. (7) holds.

$$A_2 = \frac{1 + \cos^2 \theta}{2} = 1 - \frac{3}{u} \left(\frac{u \cosh u - \sinh u}{u \sinh u} \right) \quad (7)$$

Here $u = \mu E/kT$ and μ is the dipole moment of the chromophore. For low applied fields, when $u < 1$, the approximation that $A_2 \approx u^2/(15 + u^2)$ may be used and the change in refractive index is nearly proportional to the square of the applied field. When a sinusoidal space charge field, E_{sc} , is superposed onto a uniform applied field, E_{appl} , the degree and direction of the molecular alignment, A_2 , follow the sum of both fields ($E_{total} = E_{sc} + E_{appl}$).

The amplitude of the space charge field is equal to the projection of the applied field in the direction of the grating vector and thus, for moderate fields, is proportional to the poling field E_{pol} according to Eq. (8),

$$|E_{sc}| = \frac{\sigma_p}{(\sigma_p + \sigma_d)} m |E_{pol}| \left[1 + \left(\frac{|E_{pol}|}{E_q} \right)^2 \right]^{-1/2} \quad (8)$$

where m is a parameter describing the intensity contrast, σ_p and σ_d are the photoconductivity and dark conductivity respectively, and E_q is the saturation field, which is the maximum space charge field attainable in the material [46]. The space charge field exists via an immobile charge distribution and is thus limited by the maximum density of immobile charge possible, termed the trap density. In most photorefractive organic materials under a poling field of less than $50 \text{ V } \mu\text{m}^{-1}$, the trap density does not limit the space charge field, which thus increases linearly with the applied field. The holographic refractive index contrast obtained, Δn_h , is proportional to the product of the space charge field and the applied field according to Eq. (9),

$$\Delta n_h \propto E_{sc} E_{appl} \propto E_{appl}^2 \quad (9)$$

and thus is proportional to the applied field squared.

With reference to Eq. (7), in most situations the holographic index contrast increases quadratically with the dipole moment of the chromophore. The dipole moment thus provides a parameter for material optimization, albeit at the expense of increased disorder slowing down charge transport. Transport rate appears not to be critical, however.

For a purely reorientational electro-optic response, a characteristic angle of propagation through the material will result in the optical beam experiencing a minimum holographic refractive index modulation, as illustrated in Figure 22(A). This is because the index changes for parallel and perpendicular optical polarizations are opposite in sense. Unlike the reorientational birefringence refractive index change, the refractive index change arising from the reorientationally enhanced Pockels effect is always positive in sense, such that

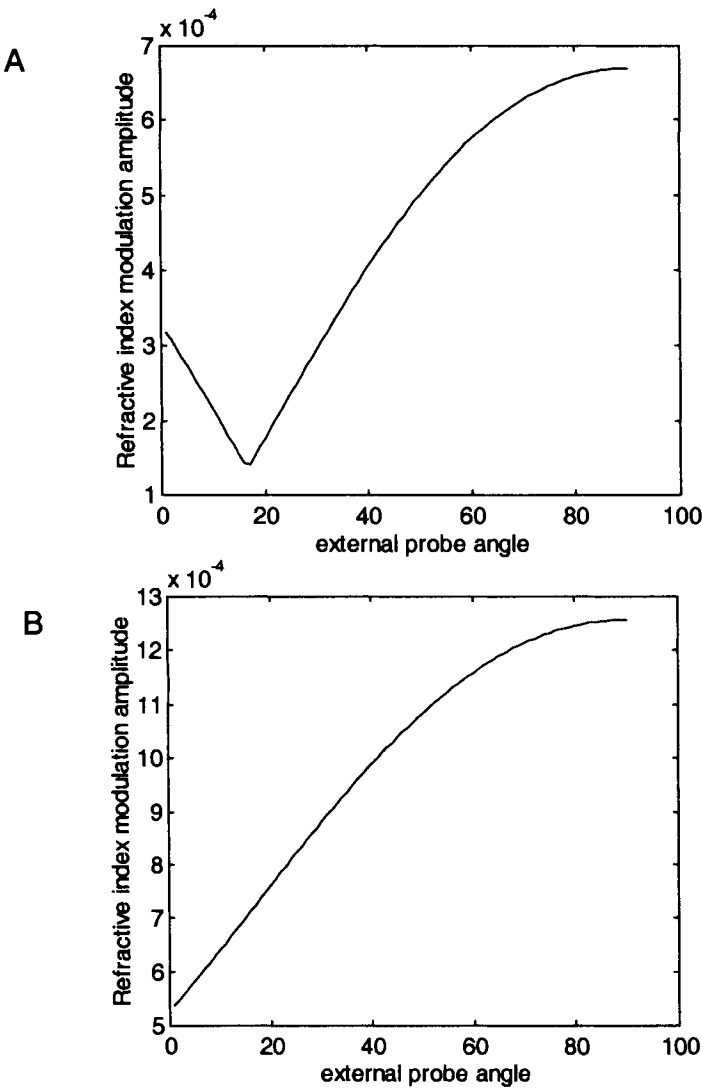

Figure 22. Refractive index modulation as a function of the external angle of the probe beam with respect to the sample normal for the material given in [20], when the writing beams are arranged at a constant 55° and 75° to the sample normal. A) angular variation if reorientational birefringence is dominant; B) angular variation if Pockels response were the primary source of index contrast.

$$\begin{aligned}\Delta n(E_{\text{opt}} \parallel E_{\text{appl}})_{\text{Pockels}} &\propto \frac{3}{2} A_2 \\ \Delta n(E_{\text{opt}} \perp E_{\text{appl}})_{\text{Pockels}} &\propto \frac{1}{2} A_2\end{aligned}\tag{10}$$

As illustrated in Figure 22(B), this does not provide a minimum in refractive index modulation. Thus, increasing the Pockels contribution to the overall birefringence also provides a route for materials development.

Not all organic photorefractive materials are reorientational. Some materials have a glass transition temperature above ambient, resulting in a fixed orientation of dipoles within the material. In these materials there are various possible procedures for recording holograms. First, a device may be heated to above the glass transition temperature before and during the recording of an index grating, and allowed to cool. The glass transition temperature is then above ambient and the chromophore alignment pattern is frozen, meaning the hologram can be read even after the applied field is removed. The main disadvantage with this method is the requirement to reheat the sample to above the glass transition temperature for subsequent hologram erasure or re-recording; furthermore any contraction upon cooling will alter the grating spacing. Alternatively, the device is heated and poled once only in a uniform poling field. A space charge field is then recorded with or without an external field. When no external poling field is used, a space charge field can be formed via charge diffusion instead of charge drift. The performance is superior when a poling field is used however, as the diffusion field is generally small in organic photorefractive materials. In this class of materials lacking reorientational enhancement, statistically uniform chromophore alignment occurs without local variations and refractive index contrast is obtained entirely from the Pockels effect. A comparison of the photorefractive performance parameters from a range of contrasting materials is presented in Table 5.

In Table 5 the difference between the photorefractive performance of a range of different reorientational materials and one permanently poled material is modest. A typical index contrast is 10^{-3} under an applied poling field of $50 \text{ V } \mu\text{m}^{-1}$ for reorientational materials. Higher index contrasts have been achieved using reorientational liquid crystals with 2×10^{-3} at the low field of $22 \text{ V } \mu\text{m}^{-1}$ but at the expense of response speed and optical quality. As discussed previously, the speed of space charge field formation in almost all cases of organic photorefractive materials depends upon the charge generation rate. For most sensitive materials, the charge generation limited rate can only be seen practically when reorientation is either fast, by the use of large concentrations of plasticizer, or slow so that the material is essentially permanently poled over the time scale of space charge field formation.

3.4.2 Holographic Optical Data Storage and Other Applications

A major application of photorefractive polymers as holographic data storage media is a real possibility. In this application two interfering laser beams write a hologram

Table 5. A comparison of the photorefractive performance parameters from a range of materials exhibiting different alignment properties and/or different mechanisms for generating a refractive index contrast.

Type	Ref.	Example material ^a	Poling field [V μm^{-1}]	Required poling field intensity [mW cm^{-1}]	Index contrast, Δn (DFWM or 2BC) ^a	Grating growth speed [s]	Optical quality	Device lifetime [months]
Reorientational guest/host polymer	[47]	49.5 % PVK 35 % PDCST 15 % BBP 0.5 % C ₆₀	100	1000	2.5×10^{-3}	0.05	Good	>5
Reorientational guest/host polymer	[45]	55 % EHDNPB 44 % PVK 1 % TNF	55	10	1.2×10^{-3}	<1	Good	>24
Permanently poled	[48]	99 % PCDI 1 % TNF	90 ^b 50 ^c	1200	9×10^{-4}	1.5	Good	>6

Reorientational liquid crystal	[49]	45 % PMMA 33 % E49 liquid crystal 21 ECZ 1 % TNF	22	51 000	2×10^{-3}	≈ 200	— ^d	— ^d

^aDFWM, degenerate four wave mixing; 2BC, two beam coupling; PDCST, (4-piperidinobenzylidene)-malononitrile; DRDCTA, 4,4'-di(N-carbazolyl)-4''-(2-N-ethyl-4-[2-(4-nitrophenyl)-1-azo] anilinoethoxy)-triphenylamine; DOP, dioctyl phthalate; PMMA, poly(methyl methacrylate); other abbreviations are defined in the text and Figures, ^belectric field applied during grating growth; required for charge generation, drift and the buildup of a space charge field, ^cpoling field applied before grating growth, in conjunction with a temperature rise to 40 °C, to provide molecular alignment, ^d—, data not available.

Figure 23. A typical holographic data storage arrangement using a photorefractive polymer device. For space charge field production, k must not be collinear with E_{pol} . During hologram recording, the object and reference beams interfere within the polymer, forming a hologram. During readout, the reference beam diffracts off the hologram and the binary image is recorded via a CCD array. The diffracted reference beam always coincides spatially with the transmitted object beam, which facilitates alignment and testing via comparison of the transmitted and diffracted beams. By utilizing an arrangement similar to that used for X-ray scattering off crystals, angle multiplexing of different holograms may be performed by rotating the reference beam by varying θ .

in the bulk of the material via the photorefractive effect. One beam, sometimes termed the object beam, is passed through a spatial light modulator to encode binary information before being focused into the material, as in Figure 23. The other beam, sometimes termed the reference beam, is a plane wave. After hologram recording, the reference beam diffracts off the hologram onto a charge-coupled device (CCD) array for information retrieval. The angle of incidence of the reference beam may be changed for multiple hologram recording in the same volume.

The material property that is most important for hologram recording is optical quality. Without good optical quality a high error rate of data retrieval occurs. The biggest issue surrounding optical quality is phase separation [45, 50], which arises as a result of large concentrations of polar molecules crystallizing out of the less polar glassy matrix. Phase separation results in severe optical scattering and can occur almost instantly after device fabrication or after a few days, weeks, or months. It can, however, be circumvented by several techniques, including the use of aliphatic groups substituted on the chromophore which are well known to prevent crystallization. Although the holographic index contrast of many organic materials is large, much larger than in inorganic photorefractive materials, field-dependent photo-generation and molecular alignment both contribute to the requirement for an applied electric field of $\sim 50 \text{ V } \mu\text{m}^{-1}$. This precludes the use of films much thicker than $200 \text{ } \mu\text{m}$. The number of holograms that it is possible to store is a function of

both the device thickness and the holographic index contrast, and currently only a few holograms can be stored in a single film. This problem can be addressed, however, by lamination of several layers to produce thicker samples for the same operating voltage, although maintaining high optical quality from laminated substrates has proved problematic [23, 51].

Consideration of electron transfer processes in holographic data storage becomes relevant when addressing the speed of hologram recording and erasure, because in many organic photorefractive systems the response speed is proportional to the photoconductivity. Thus the exact nature of mobile charge generation and transport mechanisms needs to be considered when designing fast materials.

Photorefractive polymers may facilitate other optical applications. One example is optical image correlation. Optical image correlation allows an image to be compared with a bank of images, stored holographically in the material. The images could be fingerprints of known criminals, for example, and the correlator would be able to find a match. In this technique, Fourier transforms of the two images are combined interferometrically before recovering the image. If the two input images are not correlated, there will be no output image [52]. A single image may also be split up into two parts, with one part recording a hologram in a photorefractive material. The image may be reproduced from the hologram and correlated with its original. If the original changes, then no correlation will be observed until the hologram has had sufficient time to update itself, which is dependent upon space charge field reformation as discussed above. This technique, often referred to as “novelty” filtering, provides a way of detecting changes to an image [46].

As with all fast rewritable holographic storage media, optical phase conjugation is possible. In a four-wave mixing geometry, two waves record a hologram and a third wave (the probe beam), which is collinear with one of the writing beams, is diffracted off the resulting hologram. The fourth wave is the diffracted probe beam, is collinear with the second writing beam, and has the useful property of being a phase conjugate of it. The process of phase conjugation can be used to eliminate optical distortions (Figure 24).

Another application for photorefractive polymers is optical limiting. Optical limiting prevents high light fluences from passing through the optical limiter, whilst allowing low light levels to pass unperturbed. This serves as protection against optical damage to a system or, more importantly, a user. A suitable organic photorefractive can be processed as a coating to a wide variety of devices for protection. An intense incoming beam scatters in the bulk or off the surface of the optical limiting layer. The incoming beam then forms a hologram with its scatter, which produces yet more scatter, eventually making the material opaque—which is referred to as beam fanning. Naturally, to provide any real protection against a laser, the diffraction efficiency needs to approach 100 % and the response speed needs to be fast. Low-level protection may be used to combat glare when driving.

Other interesting applications for organic photorefractives result from the phase shift between the original optical interference pattern and the holographic refractive index modulation. The phase shift is unique to photorefractive materials and allows

Figure 24. Degenerate four-wave mixing experimental arrangement and optical phase conjugation with photorefractive polymers

asymmetric two-beam coupling in which the energy from one beam couples into the other (recall Figure 2). One beam thus experiences optical loss (the pump beam) and the other experiences gain (the probe beam). If the intensity of the pump beam is much greater than that of the probe beam, then the regime of negligible depletion is applicable and small signal amplifications as high as $500\times$ are possible with a moving grating technique [53]. Such a system can be regarded as similar to a transistor and may form the basis of switching or routing in optical computing or telecommunications applications (Figure 25).

Their potential applications make organic photorefractive materials an important new class of materials. Versatile and inexpensive organic processing procedures are available to form bulk materials, thin films, or coatings. Synthesis of more optimized materials should be relatively straightforward. These factors distinguish amorphous organics as promising photorefractive materials that provide the possibility of a wide range of inexpensive devices. The rate of progress, both in understanding and in material development, is fast.

Figure 25. A) Optical switching directing telephone calls from callers 1–4 to possible receivers 5–8. B) The five individual switches utilize the two-beam coupling effect in photorefractive polymers, possibly in a waveguide geometry. By applying a gating input the signal can be redirected to an alternative output route.

4 Photoinduced Electron Transfer Initiating Systems for Free-radical Polymerization

Jerzy Pączkowski and Douglas C. Neckers

4.1 Introduction

Photoinitiated polymerization uses the energy of light for the rapid conversion of monomeric liquids to solid polymeric products. The term *photopolymerization* implies that the initiation step of a radical, cationic, or anionic chain reaction producing a macromolecule requires the absorption of a photon. Since the absorption of one photon may start the reaction of up to 10^5 monomeric units, photoinitiated polymerization is, in practice, one of the most powerful chemical amplification techniques.

In this review we will consider only photoinitiated polymerization reactions in which the chain processes involve free-radical intermediates. The process may be initiated by direct photolysis of a precursor providing free radicals by bond dissociation, or the radicals may be formed by electron transfer reactions. Panchromatic sensitization of polymerization often requires the presence of a suitable dye as the primary light absorber. This can then either transfer energy, or undergo electron transfer. Energy transfer is less common than the literature about the subject would suggest while photoinduced intermolecular electron transfer (PET) is likely more so. PET uses light to initiate electron transfer from a donor to an acceptor molecule. The process is possible because electronically excited states are both better oxidants and better reductants than their ground-state counterparts. The concept involved in PET reaction is simple: promotion of an electron from the highest occupied molecular orbital (HOMO) in the ground state to the lowest unoccupied molecular orbital (LUMO); an unpaired electron with high reduction potential in the LUMO orbital and high oxidizing potential in the residual HOMO orbital characterizes the new electronic configuration.

Translating these to the initiation of free-radical polymerization, one can anticipate that two types of reaction, oxidation and reduction, will occur with the excited state.

- 1) Dye *photoreduction* leading to subsequent polymerization was first reported in 1954 [1] when Oster identified several groups of dyes that are photoreduced in the presence of suitable reductants such as ascorbic acid and triethanolamine. The dyes included the acridines, xanthenes, and thiazines.
- 2) Dye *photooxidation* leading to subsequent polymerization requires molecules that are strong electron acceptors in the ground state. Systems composed of onium salts, reducing agents, and sensitizer/electron transfer donors are examples of such systems. They are excellent photoinitiators for the polymerization of acrylates [2–4].

There are many review articles on various aspects of photoinitiated polymerization [5–11], covering both applications of dye-sensitized polymerization and basic research studies. However, there are essentially no reviews describing, in detail, the mechanistic aspects of photoinduced electron transfer processes as applied in photocuring technologies, the PET process applied to photopolymerization processes, or the latest photoredox pairs to be used as photoinitiators.

In the present chapter we consider the inter- or intramolecular photoinduced electron transfer phenomenon. We mainly focus on photoinduced electron transfer processes that lead to the photoinitiation of polymerization, and on processes initiated by photoreduced or photooxidized excited states. We concentrate especially on a description of the kinetic schemes, a description of the reactions that follow the primary process of electron transfer, and the characteristics of intermediates formed after electron transfer. Understanding the complexity of the processes of photo-initiated polymerization requires a thorough analysis of the examples illustrating the mechanistic aspects of the formation of free radicals with the ability to start polymerization.

4.2 General Scheme

Scheme 1 is a good starting point: k_d is the rate constant representing the rate of diffusive encounters between reactants, k_{-d} denotes the rate of separation of the reactants after collision, and k_{el} is the first-order rate constant of electron transfer. The reverse step is designated by the rate constant k_{-el} , while k_r denotes the rate of return electron transfer. The key steps of the mechanism are the quenching of the chromophore excited state, either the excited singlet or triplet state, by electron transfer, and the various steps following the primary process.

Marcus [12–14] provided a simple approach allowing the prediction of the kinetics of the process, using thermodynamic parameters and spectroscopic measurements. Marcus theory assumes that bimolecular electron transfer, as shown in Scheme 1, occurs in three stages:

- 1) the formation of the precursor complex,
- 2) electron transfer, and

Scheme 1.

- 3) the change in organization of solvent cage in which electron transfer primary products exist.

It is commonly assumed that solvent reorganization will dominate electron transfer kinetically. Depending on the thermodynamics of the electron exchange, it is possible to quantitatively predict a relationship between the free energy of activation for electron transfer and the free energy associated with solvent reorganization based on Marcus theory.

Considering these principles and the interaction between the dye (chromophore) and an electron donor in the ground state and after an electron transfer process, dye photoinitiators can be classified in three different groups:

- 1) Donor–acceptor pairs with electrostatic interaction in the ground state (ground-state ion pair) but neutral after the photoinduced electron transfer process.
- 2) Donor–acceptor pairs without electrostatic interaction in the ground state and, after an electron transfer, at least one component that is neutral in the ground state.
- 3) Donor–acceptor pairs that are neutral in the ground state and charged after electron transfer. In this case the resulting product is a radical ion pair.

Since photoinitiation occurs in specific monomeric mixtures, as Marcus theory predicts, the properties of the to-be-photopolymerized mixture (polarity, viscosity, electron-donating or electron-accepting properties) may play an important role in the overall efficiency of the process. Considering this, the monomer can participate in the photoinduced electron transfer process, either as a light-absorbing chromophore, as a hydrogen atom source, or as an electron donor/electron acceptor.

The main question arising during the analysis of the photoinduced polymerization is how one can know that the dye-coinitiator system, after excitation, forms a species that is able to start polymerization chain reaction. The main factors are:

- 1) Direct observation of radical ions formed subsequent to exposure to laser flash photolysis.
- 2) Experimental evidence that the rate of photopolymerization is a function of the properties of the photo-redox pair. (Note: one should take into account only the rates that are directly affected by the PET processes.) The PET process affects

the rate up to the limit proscribed by microviscosity of the medium, which can be measured using spectroscopic probes [15–21]. Various studies of the degree of polymerization at maximum conversion indicate that for monofunctionalized monomers, at least up to 70–75 % of conversion, the overall rate of polymerization follows steady-state kinetic theory. Up to this degree of conversion there is no limitation of rate that is related to the diffusion of small molecules. For multifunctional monomers the processes that regulate the overall rate of polymerization are more complex. Therefore the relationship between PET and the rate of polymerization is limited to the initial time of polymerization (3–5 % of monomer conversion) only [22].

- 3) Fulfillment of the Marcus equation requirements for the primary process, e.g., for the process of the quenching of the dye excited state.
- 4) The presence of species able to initiate polymerization as observed by other spectroscopic tools such as electron spin resonance spectroscopy (ESR), emission spectroscopy, transient absorption spectroscopy or chemically induced dynamic nuclear polarization (CIDNP).

4.3 Dye Photoinitiators—mechanisms

4.3.1 Photoinitiating Donor–Acceptor Pairs with Electrostatic Interaction in the Ground State (Ground-state Ion Pair) and Neutral after Photoinduced Electron Transfer Process

Cyanine borate salts

Schuster and co-workers discovered that 1,4-dicyanonaphthalene solutions containing an alkyltriphenylborate salt, when irradiated, yield one-electron oxidation of the alkyltriphenylborate leading to carbon–boron bond cleavage and formation of free alkyl radicals [23]. In Gottschalk's hands [24, 25], it was shown that ionic salt pairs formed from cyanine dyes and alkyltriphenylborates (Figure 1) could be used as photoinitiators [26] that were active in the visible region of the spectrum.

Figure 1. Ionic salt pairs active as photoinitiators in the visible region.

Cyanine borates exist as tight ion pairs; certain of the salts have even been shown to form ion pairs in which the center-to-center distance between the ions is less than the sum of the individual radii [27–29]. Since the lifetime of the excited singlet state of cyanine dye is quite short, too short to allow an efficient encounter at an achievable concentration of borate in a situation in which diffusion is necessary, the self-association of the cyanine cation and borate anion is a prerequisite for efficient photoinduced reaction.

The evidence for radical formation from the cyanine borates is the following:

- 1) Irradiation of an oxygen-free benzene solution of a cyanine *n*-butyltriphenylborate at 532 nm gives *n*-octane among other products. Since octane can only form from the coupling of *n*-butyl radicals, one can conclude that irradiation of cyanine *n*-butyltriphenylborate generates free butyl radicals.
- 2) Irradiation of a benzene solution of ethylindocarbocyanine benzyltriphenylborate with an 18 ps light pulse at 532 nm gives the transient spectrum shown in Figure 2(A). Analysis of the spectrum indicates the negative absorption is due to the bleaching of the dye and a new absorption band with a maximum at 430 nm. This maximum was assigned to the cyanine dye radical. For di-*n*-butyltetramethylindocarbocyanine borates containing leaving groups that absorb in the mid-UV, e.g., di-*n*-butyltetramethylindocarbocyanine (α -methylnaphthyl)triphenylborate, laser photolysis gives a new feature. In this case, an absorption at 385 nm (see Figure 2B) that can be attributed to the 2-methylnaphthyl radical is observed. The transient absorption spectrum of this radical can be obtained by subtracting A from B (Figure 2C) [25]. Note that Scaiano et al. [32], using laser flash photolysis, in the same region observed the presence of annular type of free radicals.

Laser flash photolysis of the benzyltriphenylborate salt shows rapid bleaching of the cyanine absorption and formation of the cyanine dye radical (Figure 3). Similar experiments were carried out using vinyltriphenylborate and show that the processes occur with an efficiency significantly less than was observed for the benzyltriphenylborate. The conclusion is that the radical elimination step impacts the kinetics of the overall electron transfer process. With the tetraphenylborate salt one finds little formation of cyanine radical and the excited singlet state of the dye is nearly completely returned to the cyanine ion ground state by the end of the pulse. (Note, however, that tetraphenylborate salts with light-absorbing counterions are also good photoinitiators [30, 31].)

Figure 2. a) Transient absorption spectra recorded after excitation of di-*n*-butyltetramethylindocarbocyanine benzyltriphenylborate in benzene solution with a 18 ps laser pulse. Negative absorbance related to the bleaching of the dye absorption. The band at $\lambda_{\max} = 430$ nm is attributed to the presence of the cyanine dye radical; b) transient absorption spectra recorded after excitation of naphthyltriphenyl borate in benzene solution with a 18 ps laser pulse. The new feature is attributed to the presence of the (2-naphthyl)methyl radical; c) the difference spectrum obtained by subtracting spectrum A from spectrum B: the maximum at 385 nm is characteristic for the 2-methylnaphthyl radical. Data are taken from [25].

Figure 3. The absorption of cyanine dye (Cy) radicals monitored at 430 nm following excitation of a benzene solution with an 18 ps laser pulse. The time dependence of the absorption changes of cyanine radical for the benzyltriphenylborate case is faster than its decay. For the vinyltriphenylborate, back electron transfer and the reaction that follows electron transfer have competitive rates. For the tetraphenylborate salt, the back electron transfer process dominates after electron transfer, therefore the boron–carbon bond cleavage does not occur and almost no cyanine dye radical formation is observed (data adapted from [25]).

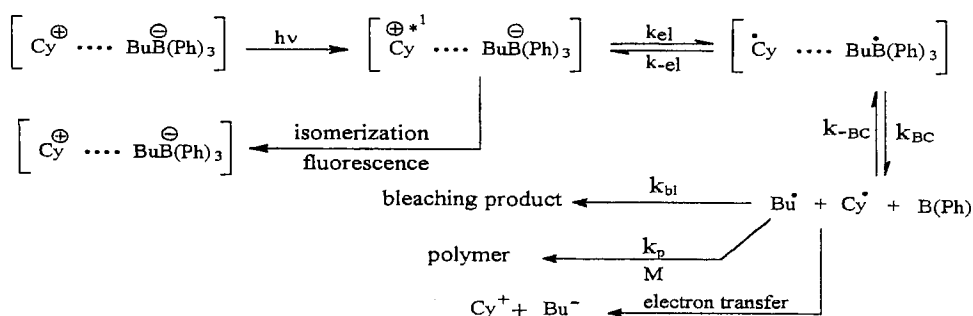

These data, by analogy, suggest the mechanism of the polymerization initiation process. Photoinduced electron transfer from the borate anion to the singlet excited state of the cyanine dye is followed by rapid cleavage of the alkyl–boron bond of the boranyl radical forming the alkyl radical (see Scheme 2), which serves as the radical chain initiator. Here k_{BC} denotes the rate of the carbon–boron bond cleavage. The reverse step is designated as k_{-BC} and k_{bl} is the rate constant of the cross-coupling step yielding bleached dye.

It is well known that a principle prerequisite for PET reactions to be allowed processes can be calculated from the Rehm–Weller [33, 34] equation (Eq. (1)). The basic Rehm–Weller requirement states that the free energy of activation for the PET (ΔG_{et}) process should have a negative value.

$$\Delta G_{et} = E_{ox}(D/D^{+}) - E_{red}(A^{-}/A) - Ze^2/\epsilon a - E_{0,0} \quad (1)$$

In Eq. (1) $E_{ox}(D/D^{+})$ is the oxidation potential of the electron donor, $E_{red}(A^{-}/A)$ is the reduction potential of the electron acceptor, $E_{0,0}$ the energy of the excited state undergoing reaction and $Ze^2/\epsilon a$ is the coulombic energy associated with the process.

Such electrochemical potentials are generally measured in a polar solvent such as acetonitrile. The electrochemical reduction of the cyanine cation (Figures 4B, 4C) in acetonitrile solution is reversible. Borate anions behave similarly (Figure 4A);

Scheme 2.

therefore the values obtained may have thermodynamic meaning. The procedure that allows calculation of the ΔG_{et} value of the process must also consider the effect of the solvent polarity on both ground and excited states. Incorporating these values gives, according to Schuster [25], the estimated values for cyanine borate ion pairs as listed in Table 1.

The absorption maximum of the cyanine dye can be changed by altering the number of conjugated alkene units linking the cyanine chromophores. This makes the cyanine borate photo-redox pair a so-called “tunable” photoinitiator, in that compounds which absorb throughout the visible and infrared spectrum can be obtained. Recently, Kabatc et al. [35] described the important features of cyanine borate photo-redox pairs (Table 2). The structures of dyes tested are shown in Figure 5.

The quantum efficiency of these cyanine borates when they are used as photoinitiators depends strongly on structure (Figure 6). However, in general, cyanine borates are not particularly efficient photoinitiators. For example the RBAX-*N*-phenylglycine photo-redox pair [36] is much more efficient. The main value of the cyanine borates is that they give substantial wavelength flexibility so they can be used in cases where polychromaticity is required (Figure 7).

Irradiation of the cyanine borates often causes bleaching, indicating that coupling of the alkyl radical with the cyanine radical [37] competes with the free-radical cage-escape process (Scheme 2). Since the bleaching process occurs with maximum quantum yields in the range $\Phi_{bl} = 0.001\text{--}0.02$, bleaching is at least one order of magnitude less efficient than is alkyl radical formation. Comparison of the quantum yields of free-radical formation (Table 1) and of the bleaching process reveals that the effect of the radical coupling reaction on the efficiency of polymerization can be neglected.

The data summarized in Table 2 indicate that the series of cyanine borates with the *n*-butyltriphenylborate counterion possess a negative ΔG_{et} value, i.e., they fulfill the basic Rehm–Weller requirements for effective photoinduced electron transfer processes. Extending this to a practical application of the Marcus equation (see

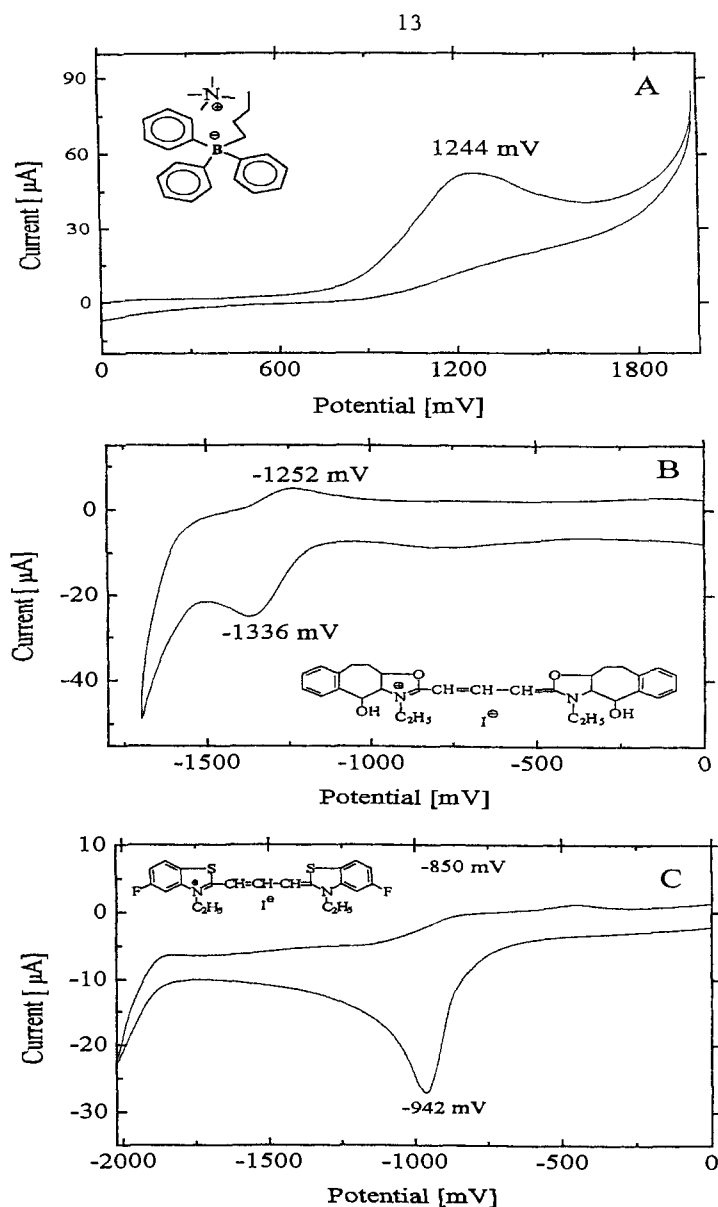

Figure 4. Cyclic voltammograms of selected compounds. The types of molecule tested are shown in insets. For measurements an electroanalytical Cypress System Model CS-1090 was used. A platinum 1 mm disk electrode was used as the working electrode and an Ag–AgCl electrode served as the reference electrode. The supporting electrolyte was 0.5 M tetrabutylammonium perchlorate in dry acetonitrile.

Figure 6. Rate of heat evolution during argon-ion laser-photoinitiated polymerization of 1-methyl-2-pyrrolidinone (MP), 9 ML of 2-ethyl-2-(hydroxymethyl)-1,3-propanediol triacrylate (TMPTA), and the dyes at a concentration of 10^{-3} M. Initiators: 1) **19**, 2) **18**, 3) **10**, 4) **16**, 5) RBAX (rose bengal derivative; prepared from rose bengal, which is first decarboxylated and then acetylated [36]).

Section 4.4) on the photoinitiation process, one can anticipate that under certain conditions (identical free radicals formed), the rules regulating the primary processes can also be applied for the secondary processes. The results presented in Figure 8 confirm this expectation. It is clear from the data (Figure 8) that the rate of polymerization as initiated by the series of cyanine borates in Table 2 increases as the driving force of the electron transfer increases. This behavior is predicted by the classical theory of photoinduced electron transfer.

Figure 7. Changes in the electronic absorption spectra of **10** (Table 2) during argon-ion laser irradiation. $I_a = 20$ mW in EtAC solution ($v = 4.0$ ML, $C = 1 \times 10^{-5}$ M, time of irradiation [s]: 1) 0.0, 2) 20.0, 3) 40, 4) 60, 5) 80, 6) 150, 7) 180 (adapted from [35]).

Figure 8. Dependence of the rate of photoinitiated polymerization on the free energy for photo-induced electron transfer from borate to the excited state of cyanine dyes, listed in Table 2.

Schuster's original measurements were performed in benzene, where the cyanine borates are known to exist as tight ion pairs. In practice, the monomers used in most photopolymerization systems possess higher dielectric constants than benzene. Therefore the degree of dissociation of the cyanine borate in monomer or mixtures of monomers is expected to be higher than it is in benzene. As an example, the data

^acalculated from the data presented in [25].

measured and calculated for cyanine hexafluorophosphate in solvents of various polarities are presented in Table 3. These data clearly show that for monomers such as methacrylates or acrylates that have dielectric constants similar to those for ethyl acetate, at concentrations used in practice (from 10^{-3} M for thick layer technology, to 0.1 M for thin layer technology), the degree of dye dissociation is quite low. Thus the cyanine dyes exist under such circumstances exclusively as ion pairs. They are organized in a molecular array that *accelerates* the rate of the photochemical primary process. Therefore, the cyanine–borate ion pair is literally a *supramolecular* photoinitiating system.

Numerous classes of cationic dyes, many of which were cyanines, have been prepared for photographic applications. Therefore a complete spectrum of such dyes is available to be considered for such purposes.

Since the initial report, photoinitiators containing other cationic dyes have appeared. These include indolenine dyes [38, 39], azulene dyes [40], pyrylium dyes, and

**Figure 9.** A cyanine borate absorbing in the infrared region [37].

Figure 10. Iodonium borate salts used as photoinitiators.

thiopyrylium dyes [41]. Research in this area is continuing, with additional patents and papers published often.

Onium borate salts

Positive ion onium salts such as diaryliodonium [42–46], triarylsulfonium [44–48], and dialkylphenacysulfonium [48] are typical electron-accepting initiators. Each can be reduced by an electron-donating light absorber such as a xanthene dye [50–52]. The photochemical reaction occurring between onium salts and light-absorbing dyes is a pure electron transfer process. Photoinitiating systems containing an onium cation and a borate anion have recently been described [53, 54] (Figure 10). The compounds were described first by DeRaaff et al. [53a] and later by Feng et al. [54], as isolable onium borate complexes with their own unique spectral characteristics. These compounds can be used to initiate the polymerization of a standard acrylate resin (Figure 11), and the decomposition can be sensitized with visible-light-absorbing sensitizers such as 2,4-diiodo-6-butoxy-3-fluorone, DIBF [53a,b].

The absorption spectra of the iodonium borates depend on the solvent [53, 54]. In acetonitrile, the absorption spectra are equal to the additive spectra obtained from the components (up to 300 nm) [55, 56]. In less polar solvents onium borates exhibit a weak, extended absorption tail in the 320–450 nm region that is attributed to an intra-ion-pair ground-state charge transfer transition from the borate anion to the iodonium cation. Photopolymerization using the iodonium borates can be effectively initiated only by UV irradiation and by violet light of the visible region.

Diaryliodonium salts [53c, 57–59] form iodobenzene, biphenyl, benzene, iodobiphenyl, and several other products during irradiation. The photolysis of butyltriphenylborate salts in the presence of electron acceptors generates biphenyl and the butyl radical [24, 54a, 60, 61], while the photolysis of the analogous tetraphenylborates also produces biphenyl as the major product.

Iodonium borates exist as tight ion pairs, so in nonpolar solvents or in solvents of moderate polarity photoinduced electron transfer should occur directly from anion

Figure 11. Photopolymerization of SLG-1 resin (70 % Ebecryl 8800-20R, 20 % tripropyleneglycol diacrylate, 10 % ethoxyethoxyethyl acrylate) irradiated by UV light (2×400 W medium-pressure Hg lamp). The photoinitiators used (see key) are listed in Figure 10.

to cation within the solvent cage. Photolysis carried out after purging with oxygen shows that decomposition is slower than that of an identical system purged with argon. Analysis of the products indicates that aryl iodide and biphenyl are the major products. Thus iodonium butyltriphenylborate salts simultaneously produce a butyl radical from the borate anion and an aryl radical from the iodonium cation. Iodonium tetraphenylborate was found to produce an aryl radical, but this radical arose only from the iodonium cation. Both radicals initiate polymerization of acrylic monomers (see below).

Sensitized photoinitiators

The first report of a charge transfer complex photoinitiating system involving onium borates was by De Raaff et al. [53a]. These workers showed the structure of the proposed charge transfer complex between a diphenyliodonium salt and a borate, indicated that a patent application had been filed [53b], and suggested that the iodonium salt–borate anion complex system would serve as a photoinitiator in the UV region of the spectrum. The UV spectrum of the complex was shown in Figure 10 of Ref. [53a]. Since the addition of iodonium salts to to-be-polymerized mixtures containing visible initiators such as DIBF and an ammonium borate greatly accelerated the rate of polymerization, a major emphasis in the work was on visible-light sensitization of the decomposition of various borate salts, including triphenylbutylborate and others, that were more soluble in monomer. Stable onium-borate complexes were readily isolated and subsequent papers by Sarker et al. [54b] and Feng et al. [54a] provided details of their use in reactions with acrylates.

The method of iodonium salt synthesis using iodonium bromide was similar to that published by Crivello and co-workers [57–59]. Symmetrical iodonium salts

Scheme 3. Syntheses of DMPIBB and DMPITB.

such as di-(*p*-methylphenyl)iodonium bromide were prepared from the reaction of toluene with potassium iodate and sulfuric acid, and followed by the addition of a solution of sodium bromide. Asymmetric iodonium bromides were prepared by direct coupling of an aromatic compound with iodobenzene diacetate in the presence of sulfuric acid, followed by mixing with a solution of sodium bromide. The iodonium bromide obtained was treated with tetramethylammonium butyltriphenylborate or sodium tetraphenylborate to produce isolable iodonium butyltriphenylborate salts or iodonium tetraphenylborate salts in high yield. The syntheses of *p,p'*-dimethylphenyliodonium triphenylborate (DMPIBB) and *p,p'*-dimethylphenyliodonium tetraphenylborate (DMPITB) are shown in Scheme 3.

The importance of this work cannot be overestimated. It led to subsequent studies of the addition of the radicals formed from these compounds to acrylates, and subsequent isolation of a number of such products. Sensitized reactions of borates using DIBF (2,4-diiodo-6-butoxy-3-fluorone) in the absence of, and presence of, iodonium salts were also part of this investigation. The rate coefficients for triplet quenching both by tertiary aromatic amines such as diisopropylidimethylaniline (DIDMA) had been measured previously by Hassoon [54c], as had the rate constants of triplet quenching by borate, by oxygen, and by iodonium salts. The deductions from this work were that DIBF triplet was quenched most rapidly by oxygen, that the rate of quenching by DIDMA and several different borates was almost identical, and that iodonium salt quenching of the triplet of DIBF did not occur. The conclusion was that in the presence of iodonium salt, DIBF triplet reduction was followed by a ground-state oxidation reaction involving the iodonium salt. In this process the radical formed following reduction either from the amine or from the borate was, depending on its lifetime, oxidized. In the absence of such a secondary reaction, the DIBF radical anion furnished the reducing electron. Both reactions caused reductive decomposition of the iodonium salt with chain reactions following that were initiated by the thereby formed phenyl radical. This is shown in Scheme 4.

Stable iodonium borate complexes show minor, but real, absorptions that differ from the sum of absorptions of compounds containing the individual ions when the

Scheme 4.

spectra are taken separately in identical solvents. The absorptions are red-shifted relative to the components, thus allowing for excited-state access using light in the near-ultraviolet region of the spectrum.

Feng isolated photoproducts from the reactions of several of the isolated iodonium borate salts when irradiated in the presence of simple acrylates. The conclusion was that aryl radicals in iodonium borates, regardless of whether or not there are aryl groups in the borate, owe their formation to the iodonium salt. To prove this point the classical physical organic method, study of a mixed system, was used. This work is important in that it confirms that products such as biphenyl find their origin only in the borate (Scheme 5). These products do not arise from free phenyl radicals such as might be formed from such borates.

Subsequently to the work on DIBF above, two other aromatic ketones, 2-chlorothioxanthone (CTX) and Michler's ketone (MK) were studied as photosensitizers for the decomposition of onium borates [55, 56]. Each absorbs light at 365 nm and their photochemistry and photophysics are well known. The time dependence of the photopolymerization of tetrahydrofurfuryl acrylate (THFA) in MeCN solution in the presence of CTX with selected onium borates (Figure 12) is shown in Figure 13. The rate of polymerization is dependent on the solvent with the fastest polymerizations observed when the onium borates are used in solvents where they form tight ion pairs. Thus higher rates are observed in the less polar CH_2Cl_2 . It is obvious that the rate of photopolymerization without sensitizer is much slower (two orders of magnitude) than that observed for sensitized photoinitiated polymerization.

As in the case of DIBF, both CTX and MK are triplet sensitizers. However, CTX appears to undergo triplet oxidation, in that a new band attributed to the

Scheme 5. Photoreaction of iodonium borate in the presence of methyl acrylate. There are no products formed via a phenyl radical (\bigcirc) path. The biphenyl that forms occurs via an intramolecular reaction and originates in the borate.

Figure 12. Onium borates used in sensitized photopolymerization of THFA (Figure 13).

Figure 13. Influence of type of ion pair (1.4×10^{-3} M) on the CTX (5.8×10^{-3} M)-sensitized photopolymerization of THFA (9.2×10^{-1} M) in MeCN solution. Rate of polymerization measured using IR spectroscopy. The light intensity (365 nm) was 1.6 mW cm^{-2} . Data from Ref. [55]

cation radical at 420 nm appears at the sacrifice of the triplet. CTX also is not bleached. The absorption spectra of CTX in an argon-saturated solution containing DPIB or DMPSB show no change with irradiation whereas solutions containing DPI or TBAB bleach. Iodobenzene and biphenyl were detected in the irradiated solution of CTX–DPIB. In the case of CTX–DMPSB, dimethyl sulfide was detected instead of iodobenzene. In the laser flash photolysis of a CTX solution containing TBAB, a new, very weak, transient absorption band at 700 nm, attributed to the presence of the CTX anion radical, was observed.

In contrast to the situation with DIBF, the free energy changes (ΔG_{et}) for the photoinduced electron transfer reactions (see Table 4) calculated using the Rehm–Weller equation [33, 34] suggest that CTX and MK may serve also as electron acceptors. It is expected that in the case of DPIB and DMPSB, a photoinduced

^a Bo^- , borate anion.

Scheme 6.

electron transfer reaction occurs between the sensitizer and either the onium cation or the borate anion of the salts.

The mechanism shown in Scheme 6 is proposed. The posulate in the case of the CTX–DPIB system is that the CTX radical cation is formed by electron transfer from the CTX triplet state to the diphenyliodonium salt, and then CTX^{•+} immediately reduces the butyltriphenylborate anion of DPIB, re-forming CTX. These processes are presumed to form the diphenyliodonium and butyltriphenylboranyl radicals, both of which are unstable. As shown by Feng's work [54a], the iodonium salt is the source of the aryl radicals, while the alkyl radical derives from the borate. CTX is recovered virtually unchanged after this process. The reaction pathway can be predicted from the values of the free energy change ΔG_{et} of radical cation formation, which is more negative ($\Delta G_{\text{et}} = -43.4 \text{ kJ mol}^{-1}$) than that calculated for the formation of the radical anion ($\Delta G_{\text{et}} = -14.5 \text{ kJ mol}^{-1}$). The opposite situation pertains in the case of CTX–DMPSB. The free energy change for the formation of the radical cation is -7.7 kJ mol^{-1} , while ΔG_{et} for CTX radical anion formation is more negative ($\Delta G_{\text{et}} = -14.5 \text{ kJ mol}^{-1}$). This result suggests that in the case of the CTX–DMPSB system, CTX^{•-} is formed by electron transfer from the butyltriphenylborate anion of DMPSB to the triplet of CTX, and CTX^{•-} is immediately oxidized by the dimethylphenacylsulfonium cation, re-forming CTX. In the case of the MK–onium borate system, a process similar to that observed with CTX–DPIB results. The above systems are effective photoinitiators because during the process one electron generates two active radicals, and because there is no consumption of the primary absorber.

Supramolecular photoinitiators of the chromophore–linker–electron donor type

Cyanine borates belong to a specific group of photoinitiating systems. Both components exist as ions, so in nonpolar solvents they exist predominantly as ion pairs. After electron transfer the [Cy[•]] [R[•]] pair of radicals diffuses from the initial solvent cage giving free radicals because it is no longer solvent-stabilized. We have shown

[61] that when one irradiates a mixture of tetramethylammonium phenyltriethylborate (TPTB) in the presence of benzophenone, one-electron oxidation of TPTB by the excited state of benzophenone leads to the formation of an alkyl radical and that such alkyl radicals, when formed, add to alkenes. In view of our previous interest in intramolecular energy transfer from benzophenone triplets within an easily dissociated perester [62–64], we studied the photochemistry of benzophenone and other chromophores, covalently linked with tertiary ammonium or triphenyl-*n*-butylgallate salts, where complexation of an electron donor occurs in close proximity to the electron-accepting chromophore. Such a supramolecular structure might permit intra-ion-pair electron transfer and this would produce a butyl radical from the borate counterion. This would efficiently initiate the free-radical polymerization [30, 31, 65–69] (see Figure 14 and Table 5).

Figure 14. Chromophore-linker-electron donor systems used as initiators of free-radical polymerization. For all the compounds shown, tetraphenylborate salts were also prepared and tested.

A detailed study was carried out on (benzophenonylmethyl)-tri-*n*-butylammonium triphenylbutylborate (BTAB). Nano- and picosecond laser photolysis demonstrated electron transfer from the borate counteranion to the excited triplet state of the benzophenone moiety. This leads to formation of a benzophenone moiety and a boranyl radical that dissociates rapidly to form butyl radicals. In the nonpolar solvent benzene the short lifetime of the triplet state (300 ps) suggests an intra-ion-pair process. The addition of 1 % MeCN caused an increase in the triplet lifetime to 1.2 ns, suggesting formation of a solvent-separated ion pair. For a 10^{-3} M solution in neat MeCN triplet decay is a function of tetrabutylammonium triphenyl-*n*-butylborate concentration.

The results clearly indicate that quenching of benzophenone triplets in polar solvents is a bimolecular process. This means that the ions exist mostly as separated ions and that the electron transfer process occurs mainly as an inter-ion-pair reaction [66, 67]. Analysis of the products after irradiation of *N*-(*p*-benzoylbenzyl)-*N,N,N*-tri-*n*-butylammonium triphenyl-*n*-butylborate (BTAB, Figure 14) indicates formation of *p,p'*-(benzoyl)dibenzyl, *p*-pentylbenzophenone and tributylamine. This indicates that electron transfer from the borate anion to the acceptor excited state leads to homolytic C–N bond scission and formation of the tertiary amine.

More recently, several other benzophenonyl and naphthyl ammonium triphenylbutyl- and tetraphenylborate salts differing only in the structure of the ammonium moiety have been tested as photoinitiators (Figure 15).

This kinetic study has shown that the borate must produce an α -aminoalkyl radical in order to be an effective initiator. All tetraphenylborates forming such radicals resemble, in efficiency, triphenylbutylborates of similar structure. Triphenylbutylborates not capable of producing α -amino radicals are inefficient radical initiators.

A representative mechanism proposed for processes occurring via either singlet or triplet states for the *n*-butyltriphenylborate compounds and involving inter- and intra-ion-pairs is given in Scheme 7.

A pre-organized donor–acceptor system is possible if one prepares a polymeric system bearing a benzophenone borate salt (Figure 16) [75]. In comparison with the low molecular weight compound at lower concentrations of the requisite benzophenone moiety, the highest activity was observed for the model compound. At

Figure 15. Chromophores that have been tested as photoinitiators. For all those shown, tetraphenylborate (denoted BPAPBa, BPPBa, and NIBa respectively) and bromide (denoted BPAPBb, BPPBb, and NIBb respectively) salts were also prepared and tested.

Scheme 7.

higher concentrations the homopolymer bearing the benzophenone borate salt gave superior performance. Polymeric systems are exceptionally stable compared with conventional, small-molecule photoinitiators. When crystalline, such polymers are insensitive to air and moisture.

4.3.2 Photoinitiating Donor–Acceptor Pair without Electrostatic Interaction in Ground State and after an Electron Transfer

We next discuss photoinitiating systems that contain a photo-redox pair but which consist of one neutral (dye) and a second charged (electron donor) component. After electron transfer a charged and a second neutral product are formed. There is

Figure 16. BTBB monomer and polymer.

no electrostatic interaction between the donor–acceptor pair in the ground state and no electrostatic interaction between the primary products formed after the electron transfer process.

In the initial description of the cationic dye–borate system [24, 76], it was postulated that electron transfer was possible because, in nonpolar solvents, dye/borate salts exist predominantly as ion pairs. Since the lifetime of the cyanine singlet excited state is quite short [24, 25], this prerequisite is crucial for effective photo-induced electron transfer. Recently initiator systems in which neutral dyes are paired with triarylalkylborate anions have appeared in the literature [77]. In the latter case, the borate ion acts as the electron donor while neutral merocyanine, coumarin, xanthene, and thioxanthene dyes act as the electron acceptors. It is obvious that these initiating systems are not organized for effective electron transfer processes. The formation of an encounter complex (EC) between excited dye and electron donor is required.

The first such system employed a neutral electron acceptor RBAX (Figure 17) (a derivative of rose bengal, prepared first by decarboxylation, and then acetylation)

Figure 17. RBAX, $E_{\text{red}}(A^{\cdot-}/A) = -0.80$ V, $E_{0,0}^T = 164$ kJ mol⁻¹.

Figure 18. Electronic absorption spectra of RBAX (0.6×10^{-4} M) in CH_2Cl_2 .

and triphenyl-*n*-butylborate as the electron donor [36]. Irradiation of this system also led to the formation of a free alkyl radical, as evidenced by the system's ability to initiate the polymerization of acrylate monomers.

Figure 18 shows that the spectral shape and the molar absorptivity are similar to those for nonpolar derivatives of rose bengal [78, 79].

The photochemical reaction between RBAX and a butyltriphenylborate salt is similar to that of eosin with the same electron donor [80–82]. This dye produces three transients in the microsecond, or longer, time regime after absorbing a pulse of light. These are the radical cation that absorbs at 454 nm, the radical anion with λ_{max} at 405 nm, and the triplet which absorbs at 560 nm [36]. Irradiation of RBAX in the presence of butyltriphenylborate results in bleaching and the appearance of an absorption band, suggesting formation of the ionic form of rose bengal. Based on the known products of the bleaching of rose bengal under reductive conditions [83] and the fact that oxidation of the butyltriphenylborate ion generates the butyl radical, formation of the coupling products between RBAX and the butyl group is to be expected. A mechanism consistent with these observations and consistent with the similarity between eosin and RBAX is presented in Scheme 8.

The photophysics of this and similar systems was clarified using new dyes based on the 3-hydroxy-6-fluorone skeleton [84–89]. Figure 19 shows absorption spectra,

as well as the spectra of transients, recorded for tetraiododihydrofluorescein (TIHF).

On the basis of the laser flash photolysis, photophysical properties of this class of dyes were established. The data are summarized in Table 6.

A working mechanistic hypothesis for photoreduction of such dyes by borate salts is shown for the photoreduction of 2,4-diiodo-6-butoxy-3-fluorone (DIBF), shown in Figure 20 [88].

When tetrabutylammonium triphenylalkylborate was used as the electron donor, the dye radical anion ($\text{DIBF}^{\cdot-}$) was observed as the only transient formed by quenching the dye triplet. The electron transfer rate calculated for the electron transfer process is $7.6 \times 10^7 \text{ s}^{-1}$, i.e., three orders of magnitude below the diffusion-controlled limit. The photobleached products and the transient phenomena observed

**Figure 20.** DIBF, $E_{\text{red}}(\text{A}^{\cdot-}/\text{A}) = -0.90 \text{ V}$, $E_{0,0}^{\text{T}} = 222 \text{ kJ mol}^{-1}$.

Scheme 9.

(nanosecond laser flash photolysis) confirm that the photoreduction of DIBF in the presence of borate salt is a one-electron transfer process. A proposed mechanism is shown in Scheme 9.

The rate of photoinitiated polymerization depends on the borate anion that is used as the coinitiator [89]. For tetraorganoborates the radical anion is formed at the same rate as the triplet state of the DIBF decays. This indicates that electron transfer is the only quenching process of the triplet. Using the Rehm–Weller equation [33, 34] and knowing the oxidation potentials of borates, the reduction potential of DIBF ($E_{\text{red}} = -0.9 \text{ V}$) and knowing its triplet energy ($E_{\text{T}} = 2.3 \text{ eV}$, 222 kJ mol^{-1}), one can calculate the free energy change (ΔG_{et}) for this electron transfer process. Negative values of ΔG_{et} indicate that reaction is thermodynamically allowed and, on the basis of the theory of the electron transfer process [12–14], one can predict the tested system should fulfill the Marcus equation. This is shown in Figure 21 for a DIBF–tetraorganoborate system.

The same trend is observed for the rate of photoinitiated polymerization (Figure 22). This suggests that:

Figure 21. Dependence of rate constant for electron transfer on the free energy change for transfer of an electron from the borate anion to the triplet state of DIBF. Data for calculation of free energy change from Ref. [89].

Figure 22. Visible-light polymerization of acrylic formulation with DBIF and tetramethylammonium tetraorganoborates as electron donors. Data from Ref. [89].

- 1) there is direct relationship between the rate of electron transfer and the rate of polymerization, e.g., the rate of the primary process is the limiting step of the photoinitiation reaction, or
- 2) the ease of oxidation of the borates is related to the stability and reactivity of the radicals formed.

A comparative analysis of the borate salts as electron donors with DIBF shows that the number of alkyl groups per boron atom determines reactivity. Dialkyldi-phenylborates initiate polymerization much more rapidly than do alkyltriarylborates and are more stable in formulations. Therefore dialkyldiarylborates are likely to be preferred over the slower, less stable alkyltriarylborates.

4.3.3 Photoinitiating Donor–Acceptor Pair Neutral in a Ground State and Charged after an Electron Transfer (Radical-ion Pair).

Each of the terms in Eq. (1) must be known in order to calculate the free energy change for a photoinitiated electron transfer process (Eq. (2)).

$$\Delta G_{\text{et}} = E_{\text{ox}} - E_{\text{red}} - E_{00} - (W_{\text{p}} - W_{\text{r}}) \quad (2)$$

E_{ox} and E_{red} are the oxidation and reduction potentials of the electron donor and acceptor, E_{00} is the energy of the excited state, W_{r} is the energy needed for bringing the reactants from infinity to the encounter distance, and W_{p} is a term associated with separating the products from the encounter to infinity [91–96].

One can find the energy needed for separating the products from encounter to infinity (W_{p}) by analyzing the equation describing the free energy change for a photoinduced electron transfer process. For a system that, after photoinduced electron transfer, forms one neutral component, this term can be set as $W_{\text{p}} \approx 0$. However, for a system that after electron transfer forms two radical ions, the term $W_{\text{p}} \neq 0$. The value of W_{p} varies with the polarity of the solvent in which the photoinduced electron transfer process is carried out. In polar solvents, one can set $W_{\text{p}} \approx 0$, and under this condition radical ions formed separated radical ions easily. For nonpolar solvents such as benzene this term can reach up to 90 kJ mol^{-1} [25]. Such a high energy will force the radical ions to remain in the solvent cage, in which different reactions may occur, than those observed for separated radical ions. This may have a critical influence on the route of processes following electron transfer.

Electron–proton transfer systems

Amines

Benzophenone–amine systems

In 1972 Sandner et al. [97] observed that the addition of a small amount of triethylamine (0.02 M) greatly increased the rate of photoinduced polymerization of methyl acrylate in *t*-butanol in the presence of benzophenone (BP). This photopolymerization was not affected by triethylamine alone, nor by BP–triphenylamine, BP–isopropanol, or BP–benzhydrol. The quantum yield of benzophenone disappearance suggests that the triplet state of BP was *quenched* by methyl acrylate. Though monomer quenching decreases the efficiency of hydrogen atom abstraction from *t*-butanol or benzhydrol, it has only a marginal effect on the efficiency of interaction between excited benzophenone and triethylamine, suggesting that something other than direct hydrogen atom abstraction from amine was involved. Mechanistic studies on the process resulted from a fundamental contribution by Cohen et al. [98] (Scheme 10).

The primary intermediates formed from the benzophenone triplet state in the presence of tertiary amines such as dimethylaniline have been observed by picosecond transient absorption spectroscopy [99]. The initial step of the process involves one-electron transfer from amine (dimethylaniline, DMA) to the triplet state

Scheme 10.

of benzophenone. The process initially generates a solvent-separated ion-radical pair (SSIRP, transient at 715 nm) consisting of the BP radical ion and the DMA radical cation. The SSIRP collapses to the contact ion-radical pair (CIRP, transient at 690 nm), during a period of 200 ps. This is manifested by a blue shift in the absorption maximum. Similar behavior was observed during the photoreduction of BP with diethylaniline or DABCO (1,4-diazobicyclo[2.2.2]octane). A rapid protonation of the ketyl radical ($\lambda_{\max} = 545$ nm) follows and this is kinetically coupled to the 690 nm transient. The rate constant for proton transfer was determined to be $2.0 \times 10^9 \text{ s}^{-1}$ for a solution of 1.0 M DMA. This is approximately three orders of magnitude faster than the corresponding rate constant for hydrogen atom transfer, even with very good hydrogen donors.

Photoinduced oxidation of amines leads to the formation of amine radical cations. These intermediates display both radical and cationic character with the N–H protons of the primary and secondary amine cation radicals being acidic. As a result, an efficient deprotonation occurs at the carbon α to the nitrogen radical cation giving aminyl radicals (Eq. (3)) [100].

Tertiary ammonium radicals are also acidic so, if α -CH protons are present in the amine, deprotonation of these intermediate products stabilizes the α -amino radicals (Eq (4)).

The formation of radicals by the deprotonation of α -amino radical cations is an important method of initiating free-radical polymerization. A mechanism of polymerization photoinitiated by the BP–amine couple (Scheme 11) involves such a process [101–104].

Gosh and Gosh [105] studied photoinitiated polymerization of methyl methacrylate initiated by the BP–*N,N*-dimethylaniline couple, and Clarke and Shanks [106] tested the influence of a variety of amines on benzophenone-initiated polymerization. That amino radicals resulted during the initiation the polymerization by benzophenone–tertiary aromatic amines was shown by Li through the use of ESR and spin-trapping methods [107]. It was shown that the rate of photoinitiated polymerization depends on the structure of the amine. More recently [108] benzophenone–tertiary aromatic amines were studied as initiators of the free-radical polymerization of polyol acrylates. Illustrative kinetic curves recorded during photoinitiated polymerization of TMPTA are shown in Figure 23.

The structures and properties of the benzophenones evaluated are summarized in Table 7. The electrochemical properties of the tertiary aromatic amines (TAA) tested are summarized in Table 8, below.

Scheme 11.

For all the BP–amine couples, measured relative rates of polymerization were plotted as a function of free energy change $f(\Delta G_{\text{et}})$ (Figure 24).

The data in Figures 23 and 24 clearly show that the efficiency of the BP–TAA as a polymerization initiator couple depends on both the benzophenone structure and the structure of the tertiary amine. Since the trend observed in Figure 24 is characteristic for kinetic phenomena in what is known as the *inverted Marcus region* [12–14, 110, 111], and since benzophenone triplet quenching cannot display this specific kinetic phenomena, one concludes that the rate of polymerization photoinitiated by

Figure 24. Relationship between the rate of polymerization (TMPTA) and the free energy change for photo-redox reaction for benzophenone–TAA initiating systems. Irradiation of the polymerization mixture was carried out using part of the UV emission (300–400 nm) of a xenon lamp (Philips CSX 150 W/1) with intensity of irradiation $I = 120 \text{ mW cm}^{-2}$.

a series of BP–TAAs is not limited by the rate of the primary process, e.g., the rate of photoinduced electron transfer.

Xanthene dye–amine systems

The photoreduction of 2,4-diiodo-6-butoxy-3-fluorone (DIBF) in the presence of *N,N*-dimethyl-2,6-diisopropylaniline is also a well documented example [88, 89]. The triplet state of the dyes, based on the 3-hydroxy-6-fluorone skeleton [87], is quenched by several electron donors, mainly aromatic amines or tertiary aliphatic amines. The process is described by a bimolecular rate constant and is accompanied by the growth of the peak at 410 nm. The position of this peak can be assigned to the dye anion radical ($D^{\bullet-}$) [112–115], indicating that the reaction between dye triplet and amines is an electron transfer process. In DIBF the dye radical anion cannot be detected on the nanosecond time scale. Instead, the neutral dye radical (DIBF $^{\bullet}$) is observed [88]. This observation permits one to conclude that, after initial electron transfer from the amine to the dye triplet, DIBF $^{\bullet-}$ and the amine cation radical are generated. The dye radical anion promotes rapid proton transfer from the carbon α to the nitrogen of the amino cation radical, giving the neutral dye radical and the amine radical [116]. In other words, the proton transfer process is too fast (large k_{H^+}) to be measured on the nanosecond time scale. The estimated electron transfer rate is equal to the rate of triplet quenching, $1.21 \times 10^8 \text{ s}^{-1}$. Flash photolysis results confirm that the photoreduction of DIBF in the presence of tertiary amine is a one-electron transfer process. Based on this, one can propose a mechanism illustrating the photoreduction of xanthene dyes in the presence of tertiary amine yielding free radicals able to initiate polymerization (Scheme 12).

Scheme 12.

This type of photoinitiating system has been studied carefully using a series of 6-alkoxy-2,4-diiodo-3-fluorones and 2-acyl- or 7-alkyl-2,4,5-triiodo-3-fluorones [117–120] as the primary light absorbers. The systems have been further evaluated as initiators for photopolymerization in the presence of a tertiary aromatic amine. Photoinitiated polymerization was triggered with an argon-ion (514.5 nm line) or He–Ne (632 nm line) laser.

A variety of amines (Table 8) and various xanthene dyes (Figure 25) were tested as visible-light photoinitiators of free-radical polymerization [108, 121]. The rate of photoinitiated polymerization depends on the type of amine used as the electron donor (Figure 26) [122, 123].

Camphorquinone–amine system

In the 1960s, the photopolymerization of polyol acrylates found a variety of applications in dentistry, including dental composite resins, adhesives, dentures, and

Figure 26. Rate of heat evolution during an argon-ion laser-initiated polymerization of 2-ethyl-2-(hydroxymethyl)-1,3-propanediol triacrylate (TMPTA) and 1-methyl-2-pyrrolidinone (MP) mixture (9:1) photosensitized by RBAX (10^{-3} M) in the presence of: 1) 4-(dimethylamino)benzophenone (0.1 M) and 2) *N,N*,3,5-tetramethylaniline (0.1 M).

Figure 27. Camphorquinone (CQ), $\Phi \approx 1.0$, $E_{\text{red}}(\text{CQ}^{\cdot-}/\text{CQ}) = -1.25$ V, $E_T = 210$ kJ mol $^{-1}$.

tiary aromatic amines. Previous correlations of the ionization potentials (IP) of quenching agents and the rate of quenching of the ketone triplet state [127] suggested that the reaction of an amine with an excited ketone involves electron transfer followed by proton transfer [128]. As a matter of fact, there is some support for this thesis in the report by Depew and Wan [129], who showed that the one-electron reduction of camphorquinone in 2-propanol produced camphorquinone radical anions [130]. Time-resolved chemically induced electron paramagnetic resonance (CIDEP) experiments suggested a dual mechanism for formation of the radical ion and evidence of both singlet and triplet precursors for the electron transfer. Partial evidence was provided by energy transfer to CQ from the benzophenone triplet which clearly showed that the CQ triplet led to $\text{CQ}^{\cdot-}$. Quenching of the CQ singlet by tertiary amine was observed using both CIDEP and fluorescence quenching ($\lambda_{\text{max}} = 505$ nm) with a bimolecular rate constant of about 2×10^8 M $^{-1}$ s $^{-1}$. Cook, observing a lack of this type of correlation for CQ–amine systems, suggested that the initiating radicals originate from a hydrogen atom abstraction reaction of the triplet state of CQ with α -dicarbonyl compounds such as α -keto esters. We find this quite unlikely. It is necessary to emphasize that photoinduced electron transfer reactions in which amines serve as ground-state electron donors are initiated by redox processes. In view of the general requirement for the

photoinduced electron transfer process that the thermodynamics of the process ($\Delta G_{\text{et}} = E_{\text{ox}} - E_{\text{red}} - E_{00}$) is governed by the amine oxidation potential (E_{ox}) and the acceptor excited-state reduction potential ($E_{00} - E_{\text{red}}$), where E_{00} is the excited-state energy and E_{red} is the reduction potential of the acceptor [100], considering a property of only one component (the ionization potentials of amines) may lead to misinterpretation and to improper conclusions. As an illustration, one can compare properties of CQ–amine and benzophenone (BP)–amine couples (see the data in Table 8 and the equation mentioned above). The free energy change (ΔG_{et}) for CQ–4,4′-bis(dimethylamino)benzophenone (MK) is 6.4 kJ mol^{-1} , while for BP–4,4′-bis(dimethylamino)benzophenone it is $-76.6 \text{ kJ mol}^{-1}$. These data suggest that electron transfer for the CQ–MK couple is thermodynamically forbidden (positive ΔG_{et}) and if free radicals are formed from amine, a process other than PET is involved during the reaction. For the BP–MK couple, since ΔG_{et} is negative, photo-reduction of BP will proceed via an electron transfer mechanism. On the other hand for the CQ–*N,N*-dimethylaniline photo-redox pair the free energy change is $-12.9 \text{ kJ mol}^{-1}$ and for BP–*N,N*-dimethylaniline it is $-96.0 \text{ kJ mol}^{-1}$. The above data indicate that for both photo-redox pairs analyzed, PET is thermodynamically allowed and the formation of free radicals for the CQ–*N,N*-dimethylaniline photo-redox pair will also be more likely occur via a photoinduced electron transfer process. This simple comparison of two different electron donors evidently shows that the prediction of the reaction mechanism on the basis of only one selected specific property might lead to uncertain conclusions. Recently CQ–amine systems were extensively studied, but research on these systems is mostly focused on their application in dentistry [131].

We find all of this mechanistic speculation quite irrelevant and suggest CQ behaves as do other α -diketones and undergoes, predominantly, α -cleavage. Our evidence for this comes from the work of Meinwold and Klingele [132], who isolated the products from the photoreactions of CQ in a number of solvents (Scheme 13). A principle observation was the CQ is totally inert in the absence of oxygen in all solvents. In the presence of oxygen, however, the products depend on the solvent and suggest formation of the peroxide. The pertinent products are the two isomeric lactones formed in benzene, and the anhydride that is produced in carbon tetrachloride as the predominant product. There is also some evidence of the photo-reduction products, *exo* and *endo*-2-hydroxyepicamphor, but these are formed mainly in methanol, and also require the presence of oxygen.

Accordingly, we suggest the principle mechanism for the catalysis of polymerization by camphorquinone, which is always used in the presence of tertiary amines, is first formation of the peroxide and then ground-state electron transfer which leads to radicals (Scheme 14). Thus the initiation of polymerization is caused by the same intermediates as it might be, were it to occur by initial electron transfer from the amine to CQ, followed by generation of an initiating radical. But oxygen quenching of the α -diketone diradical is first required (Scheme 15).

Anthraquinone–amines

Anthraquinone (AQ)–triethylamine (TEA), a photoinitiating system for the polymerization of methyl methacrylate (MMA) [133], clearly functions by electron

Scheme 13.

Scheme 14.

transfer. In the absence of TEA and in a solvent that is a poor hydrogen donor, AQ is a poor photoinitiator. Addition of amine significantly increases the photo-initiation rate in nonpolar solvents. Free-radical formation occurs from quenching of AQ triplets by TEA, leading to AQ photoreduction at a rate that is nearly diffusion-controlled [134–136]. This quenching produces radical ions which deactivate by pathways typical for such intermediates. After proton transfer, one produces the anthrasemiquinone (AQH \cdot) radical and the triethylamine radical. Such semiquinone radicals disproportionate to yield AQH $_2$ and AQ. The rate of AQ disappearance in the mixture of AQ–TEA decreases considerably in the presence of methyl methacrylate (Figures 28A, 28B). The decrease in photoreduction of AQ in

Scheme 15.

the presence of MMA can be attributed either to trapping of the AQ triplet, the contact radical-ion pair, separated radical ions and/or the AQH[•] radical. Encinas and his colleagues explained these specific behaviors as an effect of the quenching of the radical-ion pair by MMA. A simplified photopolymerization mechanism of MMA in benzene, is shown in Scheme 16 [137].

Thioxanthone–amine system

Thioxanthones (TX) absorb strongly in the near-ultraviolet region of the spectrum, and their reaction with amines comprises a bimolecular initiator system competitive with photodissociative initiators [138–150]. The photochemistry and photophysics of TX in the presence of amines are similar to that observed for other aromatic ketones, and can be summarized by the scheme proposed by Davidson [148] (Scheme 17).

Other chromophore–amine systems

Other compounds containing light-scavenging chromophores, with tertiary amines, also form couples able to initiate polymerization via photoinduced electron transfer. Safranin T (Figure 29) [151] forms radicals by the quenching of the dye singlet excited state. The rate constant of quenching is near the diffusional limit. Flash photolysis studies of safranin T in the presence of amines show the reaction involves an electron transfer process ($k_q(T)$ oscillates between 0.13×10^8 and $9.4 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$) followed by fast proton transfer to yield amine free radical.

Encinas et al. [152–154] were the first to report that the polymerization of vinyl

[133]).

monomers was photoinitiated by pyrene-amine combinations. This is one of the rare systems in which radical intermediates are formed via a singlet excited state that is not initially organized (compare cyanine borates [24, 25]). The efficiency of the system is due to the relatively long lifetime of the pyrene singlet excited state (Figure 30) [154].

The absorption band (λ_{max} 488 nm) in the transient spectrum corresponds to the pyrene radical ion ($\text{Py}^{\bullet-}$) [155, 156], while the band at $\lambda_{\text{max}} \approx 400 \text{ nm}$ is assigned to the absorption of the 1-hydro-1-pyrenyl radical (Py^{\bullet}) [157, 158]. Steady-state photolysis of pyrene in the presence of TEA leads to its disappearance, and addition of vinyl monomers decreases the rate of pyrene photoreduction. The photobleaching process follows first-order kinetics. Encinas et al. [154] suggest that the photoinitiation of polymerization by pyrene-TEA is catalyzed by the pyrene radical ion,

Scheme 16.

Scheme 17.

Figure 29. Safranin T.

Figure 30. Transient absorption spectrum of pyrene-TEA in an acetonitrile-ethyl acetate solution. Delay time after the laser pulse: A) 500 ns, B) 6 μ s. Inset: typical first-order decay trace monitored at 488 nm (data from Figure 1, Ref. [154]).

on the basis of the observation that the 488 nm $\text{Py}^{\bullet-}$ transient absorption is efficiently quenched by monomers, as well as because the monomer decreases the lifetime of $\text{Py}^{\bullet-}$ without changing its initial intensity. The mechanism (Scheme 18) involves the interaction of the pyrene radical ion, either free or formed first in the solvent cage, with a monomer, followed by the initiation of the chain reaction by the amine-derived free radical.

2,2',4,3',5,5'-Hexaarylbisimidazoles (HABIs) (Figure 31) are among the most widely used photoinitiators [11]. HABIs are both thermochromic and photochromic, and cleave either thermally or photochemically (when irradiated in the 255–275 nm or 300–375 nm regions respectively) to a pair of tetraarylimidazolyl radicals (lophyl radicals \equiv L). These radicals recombine in the dark. The L radical generated in the photodecomposition can interact with a chain transfer agent either by direct hydrogen atom abstraction or by electron transfer to produce an initiating species capable of addition to the monomer.

Photoinitiated polymerization with HABI systems can be achieved with visible light in the presence of absorbing dyes that are good electron donors [159]. Reaction

or

Figure 32. JAW.

between the HABI and sensitizer involves the singlet excited state, and the products, lophyl radicals, are formed mostly through singlet dissociation [160, 161]. A combination of ESR [162] and laser flash photolysis [162, 163] has established an electron transfer mechanism for the reaction between a HABI and sensitizer, 2,5-bis[(1*H*,5*H*-benzo [*i,j*]quinolizin-1-yl)methylene]cyclopentanone (JAW, Figure 32). (Energy transfer from JAW to the HABI on the singlet manifold is not energetically feasible because HABI absorbs at higher energy than the subject of JAW.)

It was mentioned earlier that the lophyl radical is a poor initiator of free-radical polymerization; however, it is an excellent hydrogen atom abstractor. The design of HABI compounds for photopolymerization has been optimized to exploit this difference [164].

The mechanism proposed for the photoinitiation of acrylates with HABIs takes into account that, after electron transfer, HABI dimer dissociates yielding free radical and HABI–JAW radical-ion pairs. The lophyl radicals then leave the solvent cage and react with good hydrogen donors, producing the initiating radicals. The components that remain in the solvent cage produce a radical-ion pair (stabilized by electrostatic interaction) that subsequently undergoes a proton transfer to form two radicals, one from JAW and the second from the HABI. The lophyl radical behaves as mentioned earlier, and the radical resulting from JAW is likely to react with

Scheme 19.

monomer to start polymerization. Analysis of Scheme 19 indicates one more important feature of the system, i.e., that one quantum of light generates three free radicals that are able to start free-radical polymerization.

One other important difference should be emphasized. For traditional dye-amine systems electron transfer occurs from the ground state of the amine donor to the excited state of the dye. For the HABI-JAW system the *electron transfer occurs from the excited state of amine (JAW) to the ground state of the HABI*. This specific behavior significantly differentiates this system from other dye-amine systems.

Electron-proton transfer or other secondary reaction systems

N-phenylglycines (NPGs)

Benzophenone-sensitized decarboxylation of acids of the type $RXCH_2COOH$ (where $X = O, S, \text{ and } NH$) [165-167] appears to go by electron transfer from the

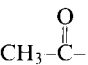

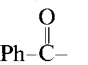

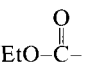

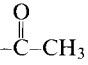

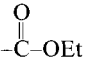

- 1) diffusion of the radical-ion pair and
- 2) intramolecular proton transfer of the radical-ion pair that is retained in the solvent cage.

A large series of *N*-phenylglycine derivatives (Table 9) was studied as electron donors in photoinduced free-radical polymerization [108]. *N*-Phenylglycine deriva-

tives were used with xanthene dyes (Figures 25, 33, and 34), as well as with camphorquinone [175].

The data in Figures 33 and 34 show typical thermodynamic properties (normal Marcus region) for the electron transfer reaction. In these examples, the rate of the process increases as the driving force of the reaction ($-\Delta G_{\text{et}}$) increases. The properties observed in Figures 33 and 34 also predict the type of radical formed after electron transfer. From studies of sulfur-containing amino acids and sulfur-containing carboxylic acids [170–175] it is known that decarboxylation occurs only if the carbox-

Figure 33. Relationship between the rate of polymerization (TMPTA/MP, 9:1) and the free energy change for photo-redox reactions for series of four different initiating systems: TDEF–NPG, ETDEF–NPG, TDPF–NPG, and BTDBF–NPG (for abbreviations see Figure 25). Data from Ref. [108].

ylic acid group is dissociated. The facts that the esters of *N*-phenylglycine derivatives and other *N*-phenylglycines behave similarly (located on the same curve in the $1 + \ln R_p = f(-\Delta G_{et})$ relationship; R_p = rate of polymerization), and that esters do not decarboxylate, suggest that under conditions of photoinitiated polymerization (medium-polarity and viscous monomer mixture), there is no separation of the radical ions. The proton transfer process yields a free radical centered on α -carbon with respect to the carboxylic group. This conclusion is supported by the quantum

Figure 35. Rate of polymerization as a function of free energy change ($-\Delta G_{et}$) for photoinitiated CQ-NPG systems. Polymerizing monomer mixture: 2-ethyl-2-(hydroxymethyl)-1,3-propanediol triacrylate (TMPTA) and ethylated bisphenol-A dimethacrylate (bis-EMA) (1:1). Polymerization was initiated by an argon-ion laser beam. Data from Ref. [175].

yield of decarboxylation, measured for *N*-phenylglycine by Nishimoto [168], which varies with the dielectric constant, ϵ , of the nonviscous solvent. When applied to a formulation of monomers (TMPTA/MP, 9:1) which possesses a dielectric constant of 13, the quantum yield of *N*-phenylglycine decarboxylation varies in the range of 7–8 %.

A similar study performed for CQ-NPG initiator systems [175] showed a rather different kinetic behavior (Figure 35). The rate of polymerization is reduced when the thermodynamic driving force ($-\Delta G_{et}$) of the process is increased, and this demonstrates “inverted-region-like” kinetic behavior. The authors explained this variation in reactivity as due to the reactivity of the free radicals formed as a result of processes occurring after electron transfer [123].

N-Phenylglycine was used as the electron donor in photopolymerizations initiated by azomethine dyes [176]. The primary light absorber, ChAD (Figure 36 and Table 10), is based on the quinoxalin-2-one residue [177, 178]. Kinetic traces recorded for

this polymerization (Figure 37) show a strong effect of electron donor structure on the rate of photoinitiation by ChAD polymerization.

Sulfur-containing amino acids (SCAA) and sulfur-containing carboxylic acids (SCCA)

To our knowledge, there is only one paper in the literature describing polymerization photoinitiated by a redox system of 4-carboxybenzophenone and sulfur-containing amino acids [182]. However, considering the potential application of these photoinitiating systems for polymerization in aqueous media and the interesting mechanism of free-radical generation, it is worth describing this system in more detail (Scheme 21).

Sensitized photooxidation of sulfur-containing amino acids in neutral aqueous solution occurs via electron transfer from the sulfur to the triplet state of the sensitizer (the mechanism can be adapted to other dye-sensitized photoinitiated polymerization). Electron transfer quenching in the system is followed mainly by diffusion of the sulfur-centered radical cation and benzophenone radical anion. Laser

Scheme 21.

flash photolysis [183] indicates two pathways of ketyl radical formation. The fast formation of ketyl radicals is ascribed mainly to the protonation of the initially produced ketyl radical anion and results from proton transfer in the radical-ion pair in the solvent cage. Slow formation of the ketyl radicals is assigned to the one-electron reduction of the benzophenone ground state by the α -aminoalkyl radical formed as a result of decarboxylation of the sulfur-centered radical cation. The formation of the ketyl radical through the reaction of the benzophenone ground state and the α -aminoalkyl radical competes with addition of the α -aminoalkyl

radical to monomer. An intermediate resulting during the process is an intermolecular three-electron-bonded radical cation formed from the sulfur-centered radical cation and neutral sulfur-containing amino acid. This intermediate is formed during a reversible process and therefore its formation does not compete with initiation of polymerization.

A series of sulfur-containing carboxylic acids demonstrate similar photophysical and photochemical features as electron donors. This is demonstrated in Table 11 [184].

Laser flash photolysis experiments allow one to establish the mechanism (see Scheme 22) of the major processes occurring during irradiation of CB-SCCA photo-redox pairs.

Photopolymerization experiments were carried out to compare the efficiency of the photoinitiated polymerization as a function of the SCCA structures. The rates of polymerization determined from the efficiencies of the photopolymerization after 6 min of irradiation are also presented in Table 11. A reference sample containing CB and other components, but without any co-initiator, did not show any polymerization. The results in Table 11 show that the rate of photoinitiated polymerization depends on the SCCA used.

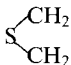

Aliphatic and aromatic sulfides

Aliphatic sulfides can be efficient co-initiators for the photoinduced polymerization induced by benzophenone [185, 186]. An exceptionally strong effect was observed for 2,4,6-trimethyl-1,3,5-trithiane (TMT). A model reaction for free-radical formation during photoreduction of an initiator triplet state by a sulfide is the photoreduction of benzophenone by dimethyl sulfide [171, 187–189]. In this process it was established that electron transfer from the sulfur atom to the triplet state of the benzophenone is a primary photochemical step. In this step, radical ions are formed. The overall quantum yields of photoproducts (ketyl radicals and radical anions) are low ($\Sigma\Phi \approx 0.26$) in aqueous solution, in the range 0.16–0.20 in mixed water–acetonitrile solution and less than 0.01 in pure acetonitrile. These results suggest that, in organic solvents, back electron transfer within the radical-ion pair to regenerate the reactants is the dominant process.

Polymerization of butane-1,4-diol dimethacrylate, sensitized by benzophenone in the presence of three different sulfides, has been described by Andrzejewska et al. [190]. The measurements show that in the absence and in the presence of propyl sulfide and 2,2'-thiobisethanol no polymer was formed. This can be explained by the effective back electron transfer process that occurs in the radical-ion pair in organic solvents. Effective polymerization was observed only in the presence of TMT. Laser flash photolysis studies performed for the benzophenone–TMT pair allow one to construct a scheme (Scheme 23) explaining characteristic features of the mechanism of polymerization initiated by the system. The results prompted the authors to study other symmetrically substituted 1,3,5-trithianes as electron donors for benzophenone-sensitized free-radical polymerization (Figure 38; Table 12) [191].

Most 1,3,5-trithianes are active co-initiators in benzophenone-induced polymerization. The most efficient is β -TMT, whose reactivity significantly exceeds that of the α -isomer. Consideration of the order of the quantum yields (Table 12) suggests

that the most active co-initiator should be β -TPT. In general, it was found that the polymerization efficiency of the co-initiators did not follow the efficiency of photo-induced free-radical formation.

4.4 Kinetics

Free-radical-initiated polymerization via an intermolecular transfer process involves many steps, including electron transfer between an excited acceptor (A) and an electron donor (D). For aromatic amines the electron transfer is followed by a

Scheme 22.

proton transfer from the donor radical cation to the dye radical anion, which yields a neutral radical initiating polymerization and the reduced radical of the dye. The radicals are formed from the electron donor and a dye. Cross-coupling between radical pairs terminates photoreaction [192]. Cross-coupling competes with the initiation of polymerization. Additionally, if the reaction takes place within the solvent cage, the products that are formed might revert to starting reactants or leave the solvent cage by ion dissociation.

Scheme 24 summarizes the possible processes that can occur during a free-radical polymerization induced via an intermolecular electron transfer process (PET) in the presence of aromatic amines; k_{dif} is the rate constant of diffusive encounters be-

Scheme 23.

tween reactants (these can dissociate with a rate constant k_{-dif}), k_{el} is the first-order rate constant of electron transfer with the reverse step denoted by the rate constant k_{-el} , and k_H is the rate constant of proton transfer between ion radicals. The cross-coupling step is designated by the rate constant k_{bl} . The polymerization step is designated by k_p and k_{ret} denotes the rate constants for the process of electron return. Scheme 24 can also be used for kinetic analysis of the photoinitiated polymerization sensitized by dye-NPGs. Generalizing, the above scheme can be applied to any system which is not stabilized in the ground state by an electrostatic interaction but that is electrostatically stabilized after electron transfer. For cyanine borates, for example, the formation of the ion pair in the ground state, and one noncharged intermediate after electron transfer, would lead to a quite different kinetic scheme (see Scheme 2).

In this section an illustrative discussion on kinetics of photopolymerization initiated via an intermolecular photoinduced electron transfer for a dye-tertiary aromatic amine initiating photo-redox couple [193] and for 4-carboxybenzophenone-sulfur-containing carboxylic acids initiating systems will be presented.

On the bases of Scheme 24, one can assume the following. Applying the steady-state approximation to the donor neutral free radical $[D^{\cdot}]$, one obtains Eq. (5),

$$\frac{d[D^{\cdot}]}{dt} = k_H[HD^{\cdot+} \cdots A^{\cdot-}] - k_{bl}[D^{\cdot} \cdots A^{\cdot}H] - k_t[D^{\cdot}M]^2 = 0 \quad (5)$$

where k_t is the constant rate of the macroradical termination process and $[D^{\cdot}M]$ is the concentration of polymeric macroradical formed from an initiating radical D^{\cdot} and monomer. For $[HD^{\cdot+}]$ the steady-state approximation yields Eq. (6), and

$$\frac{d[HD^{\cdot+}]}{dt} = k_{obs} - k_{ret}[HD^{\cdot+} \cdots A^{\cdot-}] - k_H[HD^{\cdot+} \cdots A^{\cdot-}] = 0 \quad (6)$$

thus we obtain Eq. (7),

$$k_{\text{obs}} - k_{\text{ret}}[\text{HD}^{\bullet+} \cdots \text{A}^{\bullet-}] - k_t[\text{D}^{\bullet}\text{M}]^2 - k_{\text{bl}}[\text{D}^{\bullet} \cdots \text{A}^{\bullet}\text{H}] = 0 \quad (7)$$

where k_{obs} denotes the rate constant of the simplified photochemical process represented by Eq. (8).

The traditional [7] kinetic scheme used for the description of light-induced polymerization processes is given by Eqs. (9)–(12).

The rate of reaction (9) is I_a for singlet-state or $\Phi_T I_a$ for triplet-state, reaction; the rates of processes (11) and (12) are $k_p[\text{R}^{\bullet}][\text{M}]$ and $k_t[\text{RM}^{\bullet}]^2$, respectively (I_a is the intensity of light).

In the steady state:

$$\frac{d[\text{R}^{\bullet}]}{dt} - \frac{d[\text{RM}^{\bullet}]}{dt} = 0 \quad (13)$$

and

$$\frac{d[\text{R}^{\bullet}]}{dt} = \frac{d[\text{RM}^{\bullet}]}{dt} = k_t[\text{RM}^{\bullet}]^2 \quad (14)$$

Thus

$$[\text{R}^{\bullet}] = \sqrt{\frac{2I_a}{k_t}} \quad \text{or} \quad [\text{R}^{\bullet}] = \sqrt{\frac{2I_a\Phi_T}{k_t}} \quad (15)$$

The rate of polymerization is then

$$-\frac{d[\text{M}]}{dt} = k_p\sqrt{\frac{2I_a}{k_t}}[\text{M}] \quad \text{or} \quad -\frac{d[\text{M}]}{dt} = k_p\sqrt{\frac{2I_a\Phi_T}{k_t}}[\text{M}] \quad (16)$$

This scheme does not take into consideration the rate constant for the intermolecular electron transfer process. This is possible to include by entering into Eq. (6) the relationship from Eq. (14). It should be noted that the dye radical usually

terminates the macroradical or forms the bleaching product. This is the dihydro-dye (e.g., the electron transfer is followed by a proton transfer and then the radical anion abstracts a hydrogen atom either from solvent or from other electron donor molecule.) Under these conditions $k_{bl}[\mathbf{D}^{\bullet} \cdots \mathbf{A}^{\bullet}\mathbf{H}] \ll k_t[\mathbf{RM}^{\bullet}]^2$; thus for the concentration of free radicals one obtains Eq. (17), and

$$[\mathbf{D}^{\bullet}] = \sqrt{\frac{k_{\text{obs}} - k_{\text{ret}}[\mathbf{HD}^{\bullet+} \cdots \mathbf{A}^{\bullet-}]}{k_t}} \quad (17)$$

then the rate of polymerization is given by Eq. (18).

$$R_p = -\frac{d[\mathbf{M}]}{dt} = k_p[\mathbf{M}] \sqrt{\frac{k_{\text{obs}} - k_{\text{ret}}[\mathbf{HD}^{\bullet+} \cdots \mathbf{A}^{\bullet-}]}{k_t}} \quad (18)$$

Since the process of electron return for triplet dyes requires intersystem crossing in the radical-ion pair, the rate constant of this process is negligible in comparison with the rate constants for other processes. Thus, the rate of polymerization becomes

$$R_p = -\frac{d[\mathbf{M}]}{dt} = k_p[\mathbf{M}] \sqrt{\frac{k_{\text{obs}}}{k_t}} \quad (19)$$

For further consideration it is necessary to express the rate of radical-ion pair formation as a function of light intensity, e.g., to describe the step of radical-ion pair formation starting from the acceptor molecule in its ground state (Eq. (20)).

The rate is then $k'_{\text{obs}}I_a[\mathbf{D}]$. For very high donor concentration k'_{obs} becomes practically a first-order rate constant and the rate of the process can be expressed in a simpler form as $k_{\text{obs}}I_a$.

One should take into account that back electron transfer in the successor complex might compete with a slow electron transfer step. This can be described by one composite unimolecular rate constant k_3 ($k_3 = k_{\text{ret}} + k_{\text{H}^+} + k_{\text{sep}}$). A steady-state treatment of the concentrations of the precursor and successor complexes leads to the conclusion that k_{obs} should be related to the microscopic rate constants of Scheme 1 as in Eq. (21):

$$k_{\text{obs}} = \frac{k_{\text{dif}}}{1 + (k_{-\text{dif}}/k_{\text{el}})[1 + k_{-\text{el}}/k_3]} \quad (21)$$

and in the inverted form as

$$\frac{1}{k_{\text{obs}}} = \frac{1}{k_{\text{dif}}} + \frac{1}{K_d k_{\text{el}}} + \frac{1}{K_d k_{\text{el}}} \left(1 + \frac{k_{-\text{el}}}{k_3} \right) \quad (22)$$

There are several possibilities by means of which to simplify Eq. (22). The easiest for verification is that for a reaction in the solid state or in very viscous media (diffusionless electron transfer). Under this condition Eq. (23) holds:

$$k_{\text{obs}} \cong k_{\text{el}} \quad (23)$$

If $k_{\text{obs}}I_a$ is known, one can enter Eq. (23) into Eq. (19). This gives a final equation describing the rate of initial polymerization for viscous media such as mixtures of polyol(meth)acrylates

$$R_p = -\frac{d[M]}{dt} = k_p[M] \sqrt{\frac{I_a k_{\text{el}}}{k_t}} \quad (24)$$

The limiting step, k_{el} , of the electron transfer reaction can be expressed by Eq. (25),

$$k_{\text{el}} = \chi Z \exp(-\Delta G^\# / RT) \quad (25)$$

where Z is a universal frequency factor, ca. $6 \times 10^{12} \text{ s}^{-1}$ at 25°C , χ is the transmission coefficient, k_{el} is the unimolecular rate constant describing the rate of electron transfer, and $\Delta G^\#$ is the total free energy of activation given by the Marcus equation [12–14] for neutral reactants by Eq. (26).

$$\Delta G^\# = (\lambda + \Delta G_{\text{et}})^2 / 4\lambda \quad (26)$$

Here $\Delta G^\#$ is the sum of the individual free energies:

$$\Delta G^\# = \Delta G_v^\# + \Delta G_s^\# \quad (27)$$

where the subscripts refer to the energy involving bond distortions of interacting molecules (v) and solvent changes in the ionic sphere surrounding the reactants (s = solvent); λ is defined as the total reorganization energy. Thus, $\lambda = \lambda_v + \lambda_s$, where λ_v is the inner-sphere reorganization energy referring to the energy changes of the molecule geometry during the electron transfer step, and λ_s is the outer-sphere reorganization energy which is caused by the energy change as the solvent shell surrounding the reactants rearranges. Finally ΔG_{et} is expressed by the Rehm–Weller [33, 34] equation (Eq. (1)).

Combination of Eqs. (23) and (24) gives Eq. (28),

$$R_p = -\frac{d[M]}{dt} = k_p[M] \sqrt{\frac{I_a \chi Z \exp(-\Delta G^\# / RT)}{k_t}} \quad (28)$$

and after introducing the Marcus equation (26), Eq. (29) holds:

$$R_p = -\frac{d[M]}{dt} = k_p[M] \sqrt{\frac{I_a \chi Z \exp[-(\lambda + \Delta G_{\text{et}})^2 / 4\lambda RT]}{k_t}} \quad (29)$$

Considering that the initial time of polymerization for pure monomers where $[M] \cong \text{constant}$, $[D] \cong \text{const}$, $k_p \cong \text{const}$, and $I_a \chi Z / k_t \cong \text{constant}$, one obtains Eq. (30), in logarithmic form:

$$\ln R_p = A - (\lambda + \Delta G_{\text{et}})^2 / 4\lambda RT \quad (30)$$

Equation 30 shows that if an intermolecular electron transfer process between the excited dye and an electron donor is a limiting step for photoinitiated polymerization, one should observe a parabolic relationship between the logarithm of the rate of polymerization and the thermodynamic parameter ΔG_{et} . ΔG_{et} is a measurable quantity and is accessible by experimental determination. In order to reduce the effect of diffusion-controlled termination [194–198], the effect of network formation and the Norrish–Tromsdorf effect, the initial rates of polymerization should be taken into account for further consideration. The experimental results (Figures 33 and 34) suggest that the intermolecular electron transfer process might be the limiting step in the photoinitiated polymerization. The data show that the rate of polymerization is increased when the thermodynamic driving force ($-\Delta G_{\text{et}}$) is increased. This demonstrates *normal-region* kinetic behavior.

There are, however initiating systems, which demonstrate the *inverted-region-like* kinetic behavior (Figure 39), e.g., they show that the rate of polymerization is reduced when the thermodynamic driving force ($-\Delta G_{\text{et}}$) is increased. This specific behavior is a clear indication that the rate of intermolecular electron transfer is not the limiting step for the entire process.

As observed in Figure 39, the relationship is roughly linear. Linear relationships (Figure 30) are also observed between the Hammett constant- and the phororedox properties of photoinitiating systems.

Assuming

$$\ln R_p = \rho \sigma_p \quad (31)$$

Figure 39. Inverted-region-like behavior. Relationship between the rate of polymerization (TMPTA-MP, 8:1) and the free energy change for RBAX-TAA's initiating system.

Figure 40. Relationship between Hammett constant and ΔG_{et} for RBAX-TAAs and RBAX-NPGs photoinitiating systems.

and

$$-\Delta G^\circ = \rho' \sigma_p \quad (32)$$

where ρ and ρ' are respectively, and combining Eqs. (31) and (32), gives Eq. (33)

$$\ln R_p = \frac{\rho}{\rho'} (-\Delta G^\circ) \quad (33)$$

Equation (33) clearly shows the linear relationship between the rate of polymerization and the Hammett constant, which is illustrated in Figure 39.

For processes in which the rate of polymerization is not limited by the rate of electron transfer, the equation describing the rate of polymerization, one can obtain during the analysis of simple kinetics a scheme of photoinitiated polymerization. A mechanism describing a photoinitiated polymerization via PET (not considering the kinetics of free-radical formation, because this process does not affect the rates of polymerization), that contains all the major reaction steps, can be represented by Eqs. (34)–(39).

The reactivity of free radicals depends on their structure; therefore, in the initiation of the chain Eq. (36) only some of the free radicals participate efficiently. For aromatic radicals, one can apply the Hammett equation of the description of initiation rate constant, k_i :

$$k_i = k_i^\circ e^{\rho\sigma} \quad (40)$$

where k_i is the rate constant for the initiation process for a given free radical and k_i° is the rate constant of initiation for a reference radical. Under steady-state conditions,

$$k_i^\circ [M][I_a \Phi_{A^\bullet}] = k_t [AM_{n+1}^\bullet][AM_{m+1}^\bullet] = k_t [A^\bullet]^2 \quad (41)$$

Thus the free-radical concentration is described by Eq. (42):

$$[A^\bullet] = ([\Phi_{A^\bullet}])^{0.5} (I_a)^{0.5} [M]^{0.5} (k_i^\circ e^{\rho\sigma})^{0.5} (k_t)^{-0.5} \quad (42)$$

Under this condition the rate of polymerization is

$$R_p = k_p [M]^{1.5} ([\Phi_{A^\bullet}])^{0.5} (I_a)^{0.5} (k_i^\circ e^{\rho\sigma})^{0.5} (k_t)^{-0.5} \quad (43)$$

or in logarithmic form,

$$\ln R_p = \ln A + 0.5\rho\sigma \quad (44)$$

where A for the initial time of polymerization is the sum: $\ln k_p - 0.5 \ln k_t + 1.5 \ln [M] + 0.5 \ln \Phi_{A^\bullet} + 0.5 \ln k_i^\circ + 0.5 \ln I_a$. Equation (44) clearly shows that the rate of polymerization depends on the reactivity of the free radicals yielded after the photoinduced electron transfer process.

Kinetic analysis gives additional information related to the reactivity of the free radicals obtained during the processes following a photoinduced electron transfer process. A variation in radical reactivity could be caused, for example, by their stability or their reactivity with monomer, as in the case of photoinitiation by 4-carboxybenzophenone–sulfur-containing carboxylic acid of free-radical polymerization [184].

The rate of photoinitiated polymerization can be controlled by any of the processes that limit the formation of free radicals. These processes could include the primary process, e.g., the photochemical electron transfer (PET) process, but also consequences related to this phenomenon. A good example is the photopolymerization initiated by 4-carboxybenzophenone–sulfur-containing carboxylic acid pairs. Analyzing the rate of the CB triplet-state quenching (see Table 11), one can conclude, that for these CB/SCCA systems, rates of quenching are very similar and vary only slightly in the range of $(1.0\text{--}2.0) \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$. This leads to the conclusion that, under the experimental conditions used, more than 95 % of the CB triplets are quenched by the co-initiators. The results in Table 11 show that the main photochemical channel is the diffusion apart of the radical-ion pairs, leading to the

formation of $\text{CB}^{\bullet-}$ and $\text{S}^{\bullet+}$ radical ions. This strongly suggests that the primary process should not limit the observed rate of the photoinitiated polymerization. Therefore, the differences in the measured rates of the polymerizations are likely to be affected by the yield of the secondary processes that follow PET, e.g., decarboxylation or deprotonation, and/or by the reactivity of the free radicals.

From the kinetic point of view, a mechanism describing photoinitiated polymerization via a PET process can be represented by Eqs. (45)–(51),

where ED is the electron donor (co-initiator), M is the monomer, I_A is the intensity of absorbed light, and $\Phi_{\text{R}^{\bullet}}$ is the quantum yield of free radical formation.

Assuming the rate of reaction (46) is slow relative to reactions (47) and (48), making the steady-state assumption for the total radical concentration, and taking $k_r = k_t = k'_t$, one can obtain the Eq. (52) describing the rate of polymerization [199].

$$R_p = k_p[\text{M}] \sqrt{\frac{\Phi_{\text{R}^{\bullet}} \phi_{\text{RM}^{\bullet}} I_A}{k_t}} \quad (52)$$

where $\phi_{\text{RM}^{\bullet}}$ is a branching ratio defined by Eq. (53):

$$\phi_{\text{RM}^{\bullet}} = \frac{k_i[\text{M}]}{k_i[\text{M}] + k_d} \quad (53)$$

Analyzing Eqs. (52) and (53) one can consider two specific conditions:

1) for $k_d \ll k_i[\text{M}]$, one obtains for the rate of polymerization

$$R_p = k_p[\text{M}] \sqrt{\frac{\Phi_{\text{R}^{\bullet}} I_A}{k_t}} \quad (54)$$

2) for $k_d \gg k_i[\text{M}]$, the rate of polymerization is described by Eq. (55),

$$R_p = k_p[\text{M}]^{1.5} \sqrt{\frac{k_i \Phi_{\text{R}^{\bullet}} I_A}{k_t k_d}} \quad (55)$$

Equations (54) and (55) clearly show that the rate of polymerization depends on the monomer concentration, the quantum yield of free-radical formation, and the reactivity of the free radicals produced after the photoinduced electron transfer process.

There is another interesting feature of Eqs. (54) and (55). They also show that the rate of photoinitiated polymerization is proportional to the square root of the quantum yield of free-radical formation ($\Phi_{R^{\bullet}}$). It is evident from Scheme 21 that there are two types of processes that could initiate polymerization. The quantum yield of α -CBR radical production can be taken to be equal to the quantum yield of CO_2 . The quantum yield of α -SR radical could be estimated by

$$\Phi_{\alpha\text{-SR}} = \Phi_{\text{CBH}^{\bullet}} + (\Phi_{\text{CB}^{\bullet-}} - \Phi_{\text{CO}_2}) \quad (56)$$

The co-initiators in Table 11 appear to fall neatly into two separate groups with respect to their polymerization rates; the first four have significantly larger R_p values than do the last four. In addition, the first four also have rather large quantum yields of decarboxylation compared with three of the last four co-initiators. When these observations are considered in conjunction with Eqs. (54) and (55), a tentative hypothesis is that $\Phi_{R^{\bullet}}$ can be replaced in Eqs. (54) and (55) by Φ_{CO_2} . This is equivalent to assuming that the α -CBR radicals (Scheme 21) are primarily responsible for initiating the polymerization. As a first approximation, it is also assumed that the other parameters associated with the polymerization remain the same for the different co-initiators. With these assumptions, there should be a linear relationship between R_p and $(\Phi_{\text{CO}_2})^{1/2}$. A plot of R_p vs. $(\Phi_{\text{CO}_2})^{1/2}$ is shown in Figure 41 for all the co-initiators used.

From Figure 23, it is evident that phenylthioacetic acid (point 1) has the highest rate of polymerization and the largest CO_2 yields. This is consistent with Eqs. (54) and (55) and the assumption that $\Phi_{R^{\bullet}} = \Phi_{\text{CO}_2}$. Based on the analysis above, there is only one radical, α -CBR, capable of initiating polymerization when phenylthio-

Figure 41. Relationship between the rate of polymerization of acrylamide and quantum yield of free radicals formation for 4-carboxybenzophenone (CB)-sulfur-containing carboxylic acids (SCCA) initiating system. SCCA listed in Table 11.

acetic acid is used as the co-initiator with CB. Thus the highest initiating ability is observed for the system in which there is no in-cage proton transfer process, e.g., there is no formation of radicals localized on carbons adjacent to the carboxylate ion. Several additional conclusions follow from the experimental data:

- 1) The rates of polymerization of the CB/SCCA/acrylamide systems are affected by the yields of secondary processes that follow photoinduced electron transfer, e.g., decarboxylation or deprotonation. This is in addition to the reactivity of the free radicals themselves.
- 2) The highest initiation yield is observed for the system where there is efficient diffusion of the radical-ion pairs, followed by efficient decarboxylation. The resulting radicals are localized on carbons adjacent to the sulfur atom.
- 3) Free radicals with aromatic moieties are better initiators than are the analogous aliphatic radicals.
- 4) Radicals that retain the carboxylate moiety are inefficient initiators.
- 5) Photopolymerization of these systems appears to proceed by the conventional mechanism where termination is bimolecular.

Energy and the Environment

1 Solar Energy Conversion

Michael Grätzel and Jacques-E. Moser

1.1 Introduction and Scope

There can be no question that the quality of human life is intimately associated with the ready availability of energy resources. At present, the world's energy consumption rate already exceeds the stunning figure of 6000 GW. This is expected to grow rapidly in the next decades due to the increase in demand from the developing countries. The overwhelming part of our energy supply arises from the chemical energy stored in the fossil fuels. These reserves are being rapidly depleted and their combustion has led to unacceptable levels of pollution of our environment. Further acceleration of this process would lead to disastrous climatic consequences. It is evident that the wellbeing of mankind is threatened unless renewable energy resources can be developed in the near future. Photochemistry is expected to make decisive contributions to identifying environmentally friendly solutions to the energy problem. One attractive strategy discussed below is the development of systems that mimic natural photosynthesis in the conversion and storage of solar energy. Electron transfer reactions play a vital role in the light-induced charge separation that forms the basis of this process. Our review will treat such redox processes that lead to the conversion of light to electric power and the storage of solar energy in the form of chemical fuels such as hydrogen. We shall focus our discussion on heterogeneous electron transfer reactions that occur on solid–liquid interfaces that are of particular interest in this connection. To start with, we shall briefly analyze the thermodynamic limitations of light energy conversion processes.

1.2 Efficiency Restrictions in Photochemical Conversion

The primary concern of photochemists and chemists when they run a reaction is the mass yield of product. In chemical reactions whose aim is to convert chemicals into

fuels, in electrochemical reactions which convert electricity to chemical potential or vice versa, and in photochemical reactions which convert light into chemical potential or work, the free energy yield is of equal importance. The laws of thermodynamics impose limitations on the efficiency of the conversion of light energy into chemical potential. Free energy losses in the sequence of steps during a photochemical process have several origins, which will be considered in the following order [1]: 1) nonequilibrium conditions at maximum power, 2) the entropy of the radiation source, 3) the entropy increase on scattering or absorption of the original radiation, 4) the inefficiency of energy conversion under polychromatic radiation. Further limitations associated to the storage of the chemical potential will not be discussed here.

1.2.1 Maximum Power Extraction

General to all reactions, whether photochemical or not, is the loss of free energy caused by nonequilibrium conditions due to finite power extraction. Consider a chemical reaction in which a reactant A at chemical potential μ_A is converted into a product B at chemical potential μ_B .

The rate of storage of chemical potential in the product B per unit of volume is $J \cdot \mu_B$, where the flux $J = -d[A]/dt = d[B]/dt$. If A and B are in equilibrium, the rates of the forward and back reactions are equal and the net flux to the product $J = j_f - j_b = 0$. Under nonequilibrium conditions where the forward reaction takes place with $J > 0$, there is a net overall entropy increase and $\mu_B < \mu_A$. If K is the equilibrium constant for reaction $\text{A} \rightleftharpoons \text{B}$ in ideal conditions, the change in chemical potential is given by the van't Hoff isotherm:

$$\Delta\mu = \mu_B - \mu_A = -RT \ln K + RT \ln([B]/[A]) \quad (2)$$

By putting $K = k_f/k_b$, where k_f and k_b are the rate constants of reactions $\text{A} \rightarrow \text{B}$ and $\text{B} \rightarrow \text{A}$, respectively, and by substituting the fluxes defined by $j_f = k_f [A]$ and $j_b = k_b [B]$, one obtains the expression for the free energy loss in a spontaneous reaction:

$$\Delta\mu = RT \ln(1 - \varphi) \quad (3)$$

where $\varphi = J/j_f$. The conversion power P of the reaction is given by the rate of production of chemical potential in the form of the product B at the potential μ_B : $P = J\mu_B = J(\mu_A + \Delta\mu)$. At maximum power, the reaction flux J is given by:

$$\frac{\varphi}{1 - \varphi} - \ln(1 - \varphi) = \frac{\mu_A}{RT} \quad (4)$$

and the free energy transfer efficiency η_p is:

$$\eta_p = \frac{\mu_A + \Delta\mu}{\mu_A} \quad (5)$$

The amount of chemical potential converted in a photochemical reaction is typically of the order of 1–2 eV. If $\mu_A = 1$ eV, one calculates from the latter equations $\varphi = 0.972$, $\Delta\mu = -0.093$ eV, and $\eta_p = 0.91$.

If the product B is involved in a leakage reaction to yield an undesired product C with a rate constant k_l , Eq. (4) can be rewritten:

$$\frac{\varphi - \kappa}{1 - \varphi} - \ln(1 - \varphi) = \frac{\mu_A}{RT} \quad (6)$$

with $\kappa = k_l/(k_b + k_l)$, and the free energy conversion efficiency at maximum power is:

$$\eta_p = \left[1 - \frac{k_l(\varphi - 1)}{k_b} \right] \cdot \frac{\mu_A + \Delta\mu}{\mu_A} \quad (7)$$

Assuming a leakage reaction with $k_l = k_b$, and $\mu_A = 1$ eV, one obtains $\kappa = 0.5$, $\varphi = 0.986$, $\Delta\mu = -0.110$ eV, and $\eta_p = 0.89$. If k_l is increased by a factor of ten, the efficiency decreases slightly to $\eta_p = 0.85$.

1.2.2 Limitations due to the Entropy of Light

The fact that radiation possesses entropy imposes additional constraints on the possible changes in a material system interacting with light. These constraints determine, in particular, the efficiency of processes involving the utilization of radiant energy.

Let consider a photochemical reaction without leakage, where the only fates of the product A^* are reaction to give the final product (with flux i) and reverse reaction (with flux j_b). The potential of the reactants is composed of the chemical potential μ_A of A and the potential μ_R of the radiation or, by analogy with chemical potentials, the partial molar free energy of the absorbed light quanta.

The change in potential during the light absorption process is given by:

$$\Delta\mu = \mu_{A^*} - \mu_A - \mu_R = RT \ln(1 - \varphi) \quad (9)$$

If the radiation is monochromatic at wavelength λ , its total energy is Q_R [J Einstein⁻¹] = $\mathcal{N}_A \cdot hc/\lambda$, where \mathcal{N}_A is Avogadro's number, and the entropy associated with it $\Delta S_R = \Delta Q_R/T_R$. The effective temperature T_R of the monochromatic radiation of wavelength λ and of a given spectral irradiance I_λ is expressed by Eq. (10),

$$T_R = \frac{hc}{k_B \lambda} \cdot \frac{1}{\ln \left(1 + \frac{2hc^2 \Omega}{\lambda^5 I_\lambda} \right)} \quad (10)$$

where Ω is the solid angle subtended by the source at the receiver (including any optical concentrator). The spectral irradiance I_λ is the energy of the radiation incident on a unit area per unit time and unit wavelength interval at a given wavelength λ . Thus, we may write the dimensions of I_λ as, for example, $[I_\lambda] = W \, m^{-2} \, nm^{-1}$. Equation (10) for T_R is the same as the Planck formula for a black body giving the same spectral irradiance I_λ at the same wavelength λ for unit wavelength interval and unit solid angle. Thus rays of light propagating in a specified direction and delivering at the receiver a spectral irradiance I_λ possess a temperature equal to that of a black body emitting radiation and giving rise to the same irradiance.

The entropy of the radiation ΔS_R is lost when the light disappears in the absorption process. An equivalent amount of entropy must then be created in the absorber at ambient temperature T_A . Therefore, the maximum energy available to do work at temperature T_A is given by:

$$\mu_R = \frac{Q_R(T_R - T_A)}{T_R} \quad (11)$$

The maximum possible conversion efficiency is then expressed by what appears to be simply the Carnot formula applied to radiation:

$$\eta_r = \frac{\mu_R}{Q_R} = \frac{T_R - T_A}{T_R} \quad (12)$$

The Sun delivers a spectral irradiance at the Earth's surface at AM 1.0 (air mass), without concentrator, of $1.16 \, W \, m^{-2} \, nm^{-1}$ at $\lambda = 700 \, nm$ [2]. The solid angle represented by the Sun seen from the Earth is $\Omega = 6.8 \times 10^{-5}$ steradian. From Eq. (10), one calculates in this case $T_R = 5500 \, K$, and from Eq. (12) with $T_A = 298 \, K$ one obtains $\eta_r = 0.946$. If the solar spectrum were that of a black body, all wavelengths would lead to the same values of T_R and η_r . Figure 1 shows that this condition is fulfilled only if the receiver is outside the atmosphere. At the Earth's surface, absorption by atmospheric oxygen, ozone, water, and carbon dioxide makes the structured solar irradiance spectrum deviate significantly from the ideal black-body spectrum and requires $T_R(\lambda)$ to be calculated for each wavelength.

1.2.3 Further Increase of Entropy on Absorption or Scattering

Apart from the entropy of the original radiation, a second source of entropy must be taken into account that causes losses of free energy in the course of the photochemical reaction. Upon absorption, the directionality of the radiation beam is indeed completely lost. The entropy thus increases, while the radiation temperature

Figure 1. Spectral irradiance of the Sun at mean Earth–Sun separation.

decreases. An equivalent effect is obtained when the original directional radiation concentrated in a small solid angle is scattered in all directions. The temperature of the scattered light is obtained by replacing the solid angle Ω in Eq. (10) by the value 4π corresponding to isotropic radiation at the receiver:

$$T_{Rs} = \frac{hc}{k_B \lambda} \cdot \frac{1}{\ln \left(1 + \frac{8\pi hc^2}{\lambda^5 I_\lambda} \right)} \quad (13)$$

With the same numerical values as above for the irradiance of the Sun at 700 nm, the scattering of the radiation over 4π , or (which is strictly equivalent) its absorption in a photochemical reaction, cause its effective temperature to decrease from $T_R = 5500$ K to $T_{Rs} = 1297$ K. The maximum efficiency calculated from Eqs. (11) and (12) then drops from $\eta_r = 0.95$ to $\eta_{rs} = 0.77$. The solid angle does no longer appears in Eq. (13). It should be borne in mind, however, that if the solid angle of collection is increased at the absorber by use of an optical concentrator, the measured irradiance, and hence the temperature, potential, and efficiency increase in proportion. In the same conditions as in the example above, concentration of the incident radiation by a factor of 10, for instance, translates into a rise of the radiation temperature from 1297 to 1517 K and an augmentation of the maximum conversion efficiency from 0.77 to 0.80.

Under optimum conditions of maximum power, the extraction flux $J = J_{\max}$ is given by Eq. (4), or more generally, if there are leakage processes, by Eq. (6). The global efficiency η_g of conversion of light into chemical potential at maximum

power can be expressed by:

$$\eta_g = \frac{\lambda(\mu_{A^*} - \mu_A)}{\mathcal{N}_A hc} = 1 - \frac{T_A}{T_R} - \frac{RT_A \lambda}{\mathcal{N}_A hc} \cdot \ln(4\pi/\Omega) + \frac{RT_A \lambda}{\mathcal{N}_A hc} \cdot \ln(1 - \varphi) \quad (14)$$

The last three terms represent the fractional losses due to 1) the entropy of the original radiation, 2) the entropy increase due to absorption or scattering of light, and 3) the minimum loss caused by nonequilibrium conditions at power extraction. For $\lambda = 700$ nm and AM 1.0 solar radiation, $\mu_{R_s} = 1.36$ eV. By substitution of $\mu/RT = 52.9$ in Eq. (4), one obtains $\varphi = 0.97$, the maximum global efficiency being finally estimated as $\eta_g = 1 - 0.055 - 0.180 - 0.058 = 0.71$.

If there are leakages from the excited state due to radiationless deactivation processes, Eq. (6) must be used with $\kappa = 1 - \Phi_f$, where Φ_f is the fluorescence quantum yield of A in the absence of reaction. These leakages will increase the last term of the summation in Eq. (14) and hence lower the global conversion efficiency. In the above example, if $\Phi_f = 0.5$ ($\kappa = 0.5$), the flux ratio φ is increased from 0.98 to 0.99 and the global conversion efficiency at maximum power is slightly reduced from 0.71 to 0.70.

1.2.4 Efficiency of Energy Conversion under Polychromatic Radiation

So far, calculations have assumed that the energy of the excited state is equal to that of the absorbed photon. This is not the case for polychromatic radiation when a single absorber is used. Losses due to nonabsorption or the degradation of energy in excess of the excitation energy of A^* are generally not avoidable. The simplest and most important case with which we are concerned is that of an absorber with a threshold excitation wavelength λ_t . In a somewhat idealized form, the properties of a threshold converter are:

- 1) the absorbance of the system is 0 for light with wavelength λ superior to the threshold wavelength λ_t ;
- 2) all absorbed quanta produce the same excited state with an excitation energy hc/λ_t ;
- 3) the excess energy $hc/\lambda - hc/\lambda_t$ is transferred to the medium as radiation or heat (Figure 2).

Assuming that no reaction can take place from hot excited-state levels, all absorbed photons, after degradation of excess energy, give rise to the same excitation energy hc/λ_t . The fraction θ of the energy absorbed from a polychromatic source which is available in the photochemical conversion process is given by Eq. (15),

$$\theta = \frac{\int_0^{\lambda_t} F_\lambda \frac{\lambda}{\lambda_t} d\lambda}{\int_0^\infty F_\lambda d\lambda} \quad (15)$$

Figure 2. Schematic of threshold conversion.

where F_λ is the spectral radiation flux incident on the converter from an external source. For a threshold wavelength of 700 nm and AM 1.0 solar radiation (Figure 1), the fraction $\theta = 0.38$ [3].

Obviously, the value of θ , and thus that of η_0 , depends on the value of the threshold wavelength λ_t . For a given spectral distribution of the incident radiation energy, an optimal threshold wavelength exists which yields a maximum θ . The optimal threshold wavelength for a given spectrum of the incident radiation may be determined from Eq. (15). The calculation shows, for example, that for Planckian radiation (whose spectral distribution matches that of a black body at the same temperature) with a temperature $T_R = 5200$ K (direct solar light at AM 1.5), the optimal wavelength is $\lambda_t^{\text{opt}} = 1273$ nm, and accordingly $\theta^{\text{opt}} = 0.44$. This wavelength is near the absorption threshold of silicon solar cells. Therefore, at $\lambda = 700$ nm, $T_A = 25^\circ\text{C}$, and for AM 1.5 radiation, the maximum thermodynamic overall energy conversion efficiency of these photovoltaic cells is $\eta_o = \eta_g \times \theta = 0.70 \times 0.44 = 0.31$. For green plants, the threshold wavelength determined by the optical properties of chlorophyll is 700 nm. In this case, for AM 1.5 irradiation $\theta = 0.34$, giving an overall conversion efficiency $\eta_o = 0.24$. Molecular photovoltaic devices that will be discussed in Section 1.4 are based on dye-sensitizers whose absorption threshold, for the most efficient ones, is typically $\lambda_t = 800\text{--}900$ nm. The thermodynamic limiting energy conversion efficiency for these photoconverters is thus somewhat lower than that of silicon cells and does not exceed 0.27 at any wavelength under AM 1.5 solar irradiation.

1.3 Status of Photochemical Energy Conversion Systems

Photovoltaic devices are based on the concept of charge separation at an interface of two materials having different conduction mechanisms, normally between solid-state materials, either n- and p-type regions with electron and hole majority carriers in a single semiconductor material, heterojunctions between different semiconductors, or semiconductor–metal (Schottky) junctions. In photoelectrochemical cells, the junctions are semiconductor–electrolyte interfaces. In recent years, despite prolonged effort, disillusion has grown about the prospects of electrochemical photo-

effects at these interfaces giving rise to competitive photovoltaic devices, since those semiconductors with bandgaps sufficiently narrow for efficient optical absorption of visible-light photons are necessarily insufficiently stable against photocorrosion. The width of the bandgap is a measure of the chemical bond strength. The semiconductors stable under illumination, typically the ceramic oxides of reactive metals such as titanium, therefore have a wide bandgap, an absorption edge toward the ultraviolet and a consequent insensitivity to the visible spectrum. Hence the breakthrough represented by the separation of the optical absorption and the charge separation processes in photoelectrochemistry, realized by the association of a redox dye as light-absorbing material with the wide-bandgap semiconductor. These sensitized semiconductor systems will be discussed further below.

The main thrust of the research in photoelectrochemistry during the 1970s and 1980s has been to develop systems for the splitting of water into hydrogen and oxygen. The main obstacles to direct photoelectrolysis of water are the lack of efficient light absorption (for reasonable solar efficiencies, the bandgap must be less than 2.0 eV), corrosion of the semiconductor (thermodynamically, most useful semiconductors are photochemically unstable in water), and energetics (i.e., the difficulty of matching the semiconductor band-edge energies with the H_2 and O_2 evolution reactions). The most photochemically stable semiconductors in aqueous solution are oxides, but either their bandgaps are too large for efficient light absorption or their semiconductor characteristics are poor. Semiconductors with better solid-state characteristics are typically thermodynamically unstable with respect to oxidation. However, p-type semiconductors generally offer some protection against photocorrosion, because under illumination the surface is cathodically protected. p-Type indium phosphide is stable in strong acid under illumination and H_2 evolution, but requires an external bias for water splitting. This earlier work on the photoelectrolysis of water has been reviewed [4].

1.4 Molecular Photovoltaics

In a conventional p-n junction photovoltaic cell made, for example, of silicon, the semiconductor assumes two roles simultaneously: it harvests the incident sunlight and conducts the charge carriers produced under light excitation. In order to function with a good efficiency, the photons have to be absorbed in the vicinity of the p-n interface. Electron-hole pairs produced away from the junction must diffuse to the p-n contact, where the local electrical field separates the charges. To avoid charge carrier recombination during the diffusion, the concentration of defects in the solid must be small. This imposes severe requirements on the purity of the semiconductor material, rendering solid-state devices of the conventional type quite expensive. Molecular photovoltaic systems separate the functions of light absorption and carrier transport. Light harvesting is carried out by a dye-sensitizer which initiates electron transfer events leading to charge separation. This renders unnec-

essary the use of expensive solid-state components in the system. Although they are simple from the conceptual point of view, the practical implementation of such devices must overcome several serious obstacles if the aim is to develop molecular systems which convert sunlight to electricity at an efficiency comparable with that of silicon cells, and meet the stability criteria for practical applications.

1.4.1 Mimicking Natural Photosynthesis

Natural photosynthesis is the most important of the many interesting photochemical processes known in biology. Not only was the evolution of the Earth's atmosphere dependent on it, but it is also the main route by which the free energy of the environment is made available to the living world. Green plants, algae and cyanobacteria make use of sunlight to drive a thermodynamically uphill reaction, the reduction of carbon dioxide to carbohydrates by water:

The input chemicals are carbon dioxide and water, while the output is oxygen and carbohydrates. The latter serve as a feedstock for other organic products such as wood, coal, oil, and gas constituting the World's fossil fuel reserves. It is estimated that about 10^{11} tons of carbon dioxide are assimilated annually by plants on Earth, whereby the amount of solar energy harvested by natural photosynthesis is 3×10^{18} kJ, corresponding to the continuous generation of 90 000 GW of electrical power.

Most of the key features of the manner in which photosynthetic energy conversion operates are known by now. Light-induced charge separation is achieved through judicious spatial arrangement of the pigments and elements of the electron transport chain in the tylakoid membrane. Cooperative interaction between these components allows the electron transfer to proceed in a vectorial fashion. Although strategies to design artificial photoconversion devices should not attempt to blindly imitate all the intricacies of natural photosynthesis, it is inconceivable to accomplish the challenging task of converting visible light into electrical work or chemical potential without suitable engineering on the molecular level. Efficient molecular photovoltaic devices described below and tandem systems for water cleavage by visible light presented in Section 1.5 use similar concepts to those involved in harvesting and conversion of solar energy by green plants. It is therefore useful to review the salient features of their natural analogs.

The essence of natural photosynthesis is the use of photochemical energy to split water and reduce CO_2 . Molecular oxygen is evolved in the reaction, although it appears at an earlier stage in the sequence of reactions than the reduction of carbon dioxide. Photochemical processes produce compounds of high chemical potential, which can drive a multistep synthetic sequence from CO_2 to carbohydrate in a cyclic way. Reaction (16) is quite endoergic and thus thermodynamically very improbable in the dark ($\Delta G^0 = 522$ kJ per mole of CO_2 converted). Production of one molecule of oxygen and concomitant conversion of one molecule of carbon dioxide require the transfer of four electrons:

Reaction (16) is the sum of reactions (17) and (18). Clearly, if each photon harvested by the system can lead to the transfer of one electron, then a minimum of four photons are required for the conversion of each CO_2 molecule. Experimental measurements of the quantum yield indicate that eight photons are actually needed, suggesting that two photons are used for each electron transfer and that a two-step process is taking place with long-lived intermediates coupling the steps.

Photosynthesis comprises a light-induced and a dark reaction. The first, called photophosphorylation, involves the two-electron reduction of nicotinamide adenine dinucleotide phosphate (NADP^+) by water, to produce NADPH and oxygen. The redox reaction is coupled to the generation of adenosine triphosphate (ATP) from adenosine diphosphate (ADP):

where P stands for the phosphate PO_4^{3-} anion. This light-driven reaction takes place in the tylakoid membranes located in the interior of the chloroplasts of plant cells. The photosynthetic unit assembled in these membranes is composed of antenna pigments for light energy harvesting, i.e., chlorophyll and carotenoids, as well as a reaction center consisting of two photosystems. The photons absorbed by the antenna pigments are first transferred to a chlorophyll dimer that is part of the reaction center. The electronic excitation causes electrons to be ejected from the chlorophyll dimer and then passed on to various electron-transferring mediators. The judicious spatial arrangement of these components allows the electrons to be transferred in a vectorial fashion from the inner to the outer part of the membrane (Figure 3). The positive charges left behind produce oxygen and protons from water while the electrons reduce NADP^+ to NADPH. The latter is nothing else but a hydride, i.e., a stored form of hydrogen. The pH gradient generated across the membrane is used to store additional energy via the phosphorylation of ADP to ATP. There are two light-absorbing photosystems, PS I and PS II, each containing chlorophyll, that operate in series. Photoexcitation of PS II initiates a series of redox steps resulting in the transfer of electrons from water to plastoquinone (pQ). This product is the electron donor for PS I, which under illumination performs the reduction of NADP^+ to NADPH (Figure 4).

The dark reaction, known as the Calvin cycle, uses the reducing power of NADPH as well as the free energy stored in the ATP to assimilate carbon dioxide in the form of carbohydrates. The way by which Nature achieves carbon fixation is via the reaction of CO_2 with ribulosebiphosphate (RuBP) to give two molecules of 3-phosphoglycerate, a process which is catalyzed by the enzyme RuBP-carboxylase. The phosphoglycerate is converted further to fructose 6-phosphate, the final product of the Calvin cycle. The overall reaction, despite its complex mechanism, corresponds to the simple Eq. (16) above.

Most green plants operate with photosynthesis efficiencies of a few percent. Eucalyptus trees are particularly efficient in this respect and reach as high as 5 %,

Figure 3. Functional organization of photosystem II in protein complexes contained in the thylakoid membrane. Excitation energy is harvested by chlorophyll (Chl) and carotenoids (Car) molecules and transferred to the special pair (Chl_2). Vectorial electron transfer across the membrane takes place from excited Chl_2^* to plastoquinone (pQ) via pheophytin (Ph) and quinone (Q) electron mediators.

Figure 4. The Z-scheme of green plant photosynthesis: coupling of the two pigment systems, I and II. P_{680} and P_{700} = chlorophyll; pQ = plastoquinone; Cyt = cytochrome; pC = plastocyanine; Fdb, Fds = ferredoxin.

Figure 5. Schematic representation of the principle of the nanocrystalline injection photovoltaic cell showing the electron energy level in the different phases. The cell voltage ΔV obtained under illumination corresponds to the difference in the Fermi level of the semiconductor and the electrochemical potential of the redox couple (M^+/M) used to mediate charge transfer between the electrodes.

one-fifth of the thermodynamic maximum energy conversion efficiency discussed in Section 1.2. In plant leaves, sunlight is only weakly absorbed by chlorophyll and carotenoid molecules. These dyes, however, are contained in the membrane of stacked pancake-shaped vesicles, the thylakoids, that are grouped in the chloroplast cells. Efficient harvesting of sunlight is eventually achieved by absorption through numerous pigment layers. Furthermore, light harvesting and charge separation functions are carried out separately in the natural photosynthetic system, and end up in the transport of opposite charges on both sides of the thylakoid membrane.

In molecular photovoltaic devices discussed hereafter, the incident photons excite a dye-sensitizer that injects an electron into the conduction band of a wide-bandgap semiconductor. Positive holes left in the dye are then carried away by an electrolyte mediator or conducted through a hole-transporting medium (Figure 5). Mimicking the key features of natural photosynthesis, these devices rely on a mesoporous film structure to ensure efficient harvesting of sunlight using a molecular absorber. As well, light absorption and electron collection functions are separated in such systems. Electron injection into semiconducting nanoparticles which achieves charge separation across the solid/electrolyte interface is analogous to charge separation in the photosynthetic membrane.

1.4.2 Mesoscopic Oxide Semiconductor Films

Light harvesting by monomolecular dye layers

Absorption of incident radiation by a molecular sensitizer adsorbed as a monolayer to the surface of a solid come up against the fundamental problem of a limited

light-capture cross-section of the dye molecules. The absorption cross-section σ [cm^2] is related to the decadic molar extinction coefficient ε [$\text{L mol}^{-1} \text{cm}^{-1}$] by Eq. (20):

$$\sigma = \varepsilon \times 1000 \times \ln(10) / \mathcal{N}_A \quad (20)$$

where \mathcal{N}_A is Avogadro's number. Since ε characterizes molecules in solution whose spatial orientation is random, favorable orientation of the chromophores upon adsorption on a surface can lead to an increase of the effective cross-section by at most a factor of two. Typical ε values for dyes lie between 10^4 and $2 \times 10^5 \text{ L mol}^{-1} \text{cm}^{-1}$, yielding for the light-capture cross-section values between 0.0038 and 0.15 nm^2 . The area the sensitizer molecules occupies on the surface of the supporting solid is much larger, e.g., about $1\text{--}2 \text{ nm}^2$. Hence, at most a few percent of the incident light can be absorbed. Deposition of a multilayer of dye on the surface in order to increase its light absorption is generally a mistaken tactic, since energy transfer between sensitizer molecules rarely gives rise to efficient antenna effects and outer dye layers act only as a light filter, with no contribution to photocatalysis.

A successful strategy to solve the problem of light absorption through such molecular layers is found in the application of films of high internal surface area, consisting of nanocrystalline oxide particles with a diameter of $10\text{--}20 \text{ nm}$. The mesoporous morphology of the layer plays a crucial role in the harvesting of sunlight. Depending on film thickness, their real exposed surface area can easily be made 1000 times larger than the apparent geometric one. When light penetrates the dye-covered solid "sponge", it travels through hundreds of adsorbed dye monolayers and is efficiently captured. Consider the case of a $3 \mu\text{m}$ thick mesoporous film whose effective surface area is 300 times larger than that of a compact solid and that the film is covered by a monolayer of dye molecules each of which occupies an area of 1 nm^2 . On the geometric projection of such a rough surface a dye coverage of $\Gamma = 3 \times 10^{16} \text{ cm}^{-2}$ is reached. Its absorbance A [—] is given by Eq. (21):

$$A = \Gamma \times \sigma \quad (21)$$

where Γ is the chromophore surface concentration and σ its absorption cross-section. Suppose that the dye molecule at the wavelength of its absorption maximum has a light-capture cross-section of $5 \times 10^{-17} \text{ cm}^2$ ($\varepsilon = 1.3 \times 10^4 \text{ L mol}^{-1} \text{cm}^{-1}$). As a result the absorbance of the film would be $A = 1.5$. Neglecting light scattering by the film, its light-harvesting efficiency (*LHE*), namely the absorptance, is given by Eq. (22), implying that 97% of the incident photons are absorbed.

$$LHE = 1 - 10^{-A} \quad (22)$$

Preparation and morphology of mesoscopic oxide semiconductor films

Over recent years, nanocrystalline materials have attracted increasing attention from the scientific community because of their extraordinary physical and chemical

properties. These result from the ultrafine structure (i.e., grain size < 50 nm) of the materials. Nanocrystalline electronic junctions are constituted by a network of mesoscopic oxide or chalcogenide particles, such as TiO_2 , ZnO , Fe_2O_3 , Nb_2O_5 , WO_3 and Ta_2O_5 , or CdS and CdSe , which are sintered together to constitute transparent mesoporous films, typically a few microns thick. As electrons can rapidly percolate between interconnected particles through the film, the entire surface-adsorbed molecular layer can be electronically addressed. Charge transfer events involving adsorbed molecule can thus be induced through the nanocrystalline support and recorded as electrical current. Optical monitoring is also facile as the signals arising from the grafted molecules are greatly enhanced due to the huge internal surface area of the junction. For 15 years titanium dioxide has been the semiconductor of choice. The material has many advantages for sensitized photo-electrochemistry: like most wide-bandgap oxides, it is stable and does not tend to corrode in liquid electrolytes. The Lewis acidity of its surface affords a convenient handle for attachment of dye molecules by way of electron-rich anchoring groups. Moreover, TiO_2 is a low-cost, widely available, nontoxic, and even biocompatible, substance that is widely used in domestic applications.

Mesoporous oxide films are commonly produced via a sol-gel type of process involving a hydrothermal step. The procedure is illustrated for TiO_2 in Figure 6. The initial precipitation of the oxide involves controlled hydrolysis of a Ti(IV) compound, usually an alkoxide such as titanium tetraisopropoxide or TiCl_4 , followed by peptization. Autoclaving of the sols obtained (heating at $200\text{--}250^\circ\text{C}$ for 12 h) allows for controlled growth of the primary particles and improves their crystallinity. During this hydrothermal growth, smaller particles dissolve and fuse to large particles by a process known as "Ostwald ripening". After partial removal of solvent and addition of a binder, the sol is ready for deposition on the substrate. For the latter, a conducting glass (sheet resistance = $8\text{--}10\ \Omega/\text{square}$) is often used. The sol is deposited by doctor blading or screen printing and briefly fired in air. During the firing, the binder and possible organic contaminants are burned out, thus producing a clean, mostly dehydroxylated, oxide surface. The film thickness is typically $5\text{--}10\ \mu\text{m}$ and the film mass about $1\text{--}2\ \text{mg cm}^{-2}$. The electronic contact between particles is produced by sintering during the firing treatment at about 450°C . A mesoporous structure with a very high effective surface area is thereby formed. Analysis of the layers shows their porosity to be about 60 % and the average pore size 12 nm. Figure 7 displays the morphology of such a nanocrystalline TiO_2 (anatase) layer deposited on a transparent conducting oxide (TCO) glass. A large fraction of the particles has a bipyramidal shape, which is typical of anatase crystalline form. The exposed surface faces are mostly oriented in the (101) direction [5]. The mean particle diameter is 20 nm in this case. Their size and morphology can be adjusted by varying the conditions of the sol-gel process used for film preparation. Films of self-assembled rodlike particles have been obtained when the hydrothermal treatment of the TiO_2 colloid is done in the presence of tetramethylammonium hydroxide at $190\text{--}230^\circ\text{C}$. The rodlike particles were observed to have (100) faces terminated from the (001) side. The pores diameter of the film in this case is 4 nm with a very narrow size distribution [6].

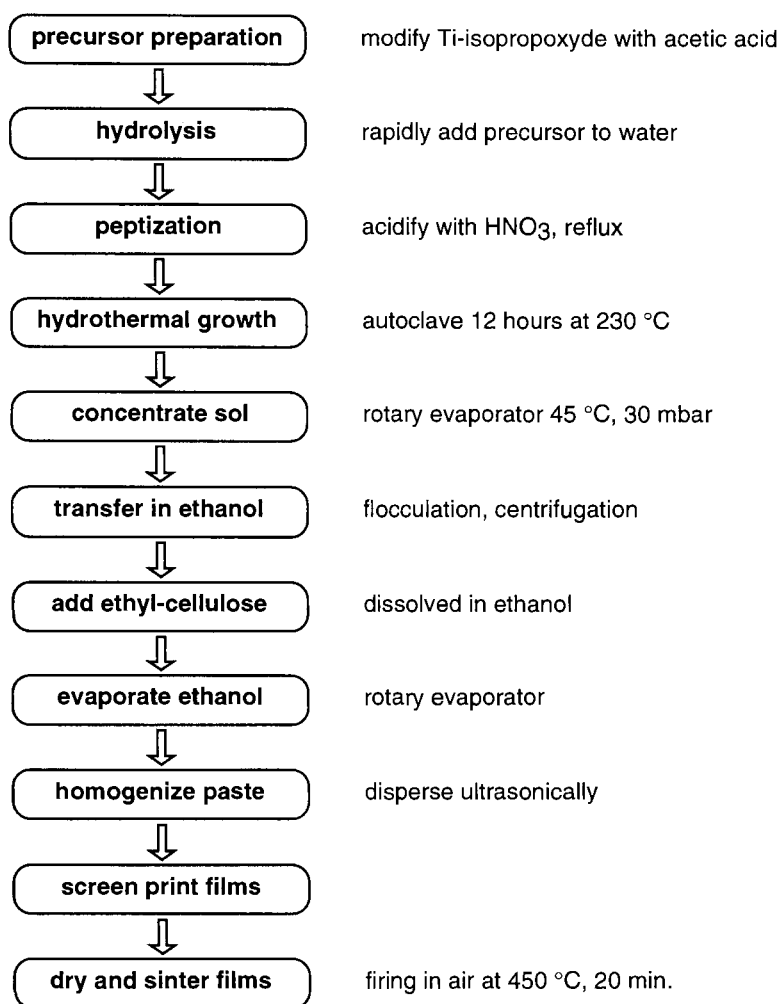

Figure 6. Outline of the steps involved in the preparation of mesoporous TiO₂ film electrodes.

1.4.3 Photoinduced Charge Separation at the Solid/Electrolyte Interface

The use of mesoporous oxide films as a substrate to anchor the dye molecules allows sunlight to be harvested over a broad spectral range in the visible region. Similarly to chlorophyll in the green leaf, the dye acts as an electron transfer sensitizer. Upon excitation by light, it injects an electron into the conduction band of the oxide, resulting in the separation of positive and negative charges. Charge transfer from photoexcited dyes into semiconductors was discovered more than a century

Figure 7. Scanning electron micrograph of a mesoporous TiO_2 film supported on conducting glass. The predominant facets of the anatase crystals have the (101) orientation.

ago in a famous experiment by Moser [7]. He observed that the photoelectric effect reported earlier by Becquerel on silver plates [8] was enhanced in the presence of erythrosin dye. The one-page publication describing his observations is shown in Figure 8. A few years before, Vogel in Berlin had associated dyes with the halide semiconductor grains to make them sensitive to visible light [9]. This led to the first panchromatic film, able to render the image of a scene realistically in black and white [10]. However, the clear recognition of the parallelism between the two procedures, a realization that the same dyes in principle can function in both systems [11], and a verification that their operating mechanism is by injection of electrons from photoexcited dye molecules into the conduction band of the n-type semiconductor substrates [12] date to the 1960s. In subsequent years the idea developed that the dye could function most efficiently if chemisorbed on the surface of the semiconductor [13, 14]. The concept emerged of using dispersed particles to provide a sufficient interface [15], then photo-electrodes were employed [16, 17]. Finally, the use of nanocrystalline TiO_2 films sensitized by a suitable molecular dye provided an important technological breakthrough [18]. These mesoporous membranes have allowed in effect for the first time the development of a regenerative photoelectrochemical cell based on a simple molecular light absorber, which attains a conversion efficiency commensurate with that of silicon-based photovoltaic devices, but at a much lower cost.

Molecular engineering of dye sensitizers

Many studies based on the observed bulk photoelectrochemical effects and on direct probing of the processes occurring at the solid surface have provided firm evidence that the sensitizing mechanism involves as a primary step electron or hole injection by the electronically excited sensitizer molecule (S^*) into the semiconductor (SC).

Notiz über Verstärkung photoelektrischer Ströme durch optische Sensibilisierung.¹

Von Dr. James Moser.

Aus dem physikalisch-chemischen Laboratorium der Wiener Universität.

(Vorgelegt in der Sitzung am 23. Juni 1887.)

Ich erlaube mir mitzutheilen, dass ich die von Herrn E. Becquerel entdeckten photoelektrischen Ströme erheblich dadurch verstärken konnte, dass ich die beiden chlorirten, jodirten oder bromirten Silberplatten in einer Farbstofflösung, z. B. Erythrosin, badete.

Beispielsweise war zwischen zwei chlorirten Silberplatten die elektromotorische Kraft im Sonnenlicht 0·02, zwischen zwei anderen in gleicher Weise behandelten, aber gebadeten Platten 0·04 Volt.

Bisher sind nur an jodirten Platten von Herrn Egoroff elektromotorische Kräfte beobachtet, und zwar bis $\frac{1}{15}$ Volt. Ich konnte bei jodirten und bromirten Platten durch Baden in Erythrosin $\frac{1}{4}$ Volt erreichen.

Ich halte es für meine Pflicht, schon an dieser Stelle Herrn Max Reiner, der mir bei diesen Versuchen assistirt, meinen verbindlichsten Dank auszusprechen.

¹ Akadem. Anzeiger Nr. XVI.

Figure 8. A copy of the 1887 publication by J. Moser on the amplification of photoelectric currents by optical sensitization of silver halides by erythrosin [7]. The system described in this paper was indeed the first dye-sensitized photovoltaic solar cell.

Alternatively, charge injection into the semiconductor can involve the reductive or oxidative quenching of the dye excited state by a redox-active species (a *super-sensitizer*) followed by thermal interfacial electron transfer [19].

In the case of the injection of an electron from the excited state of a molecular sensitizer into the conduction band of a semiconductor (Eq. (23)), the thermodynamics of the photo-redox reaction requires the oxidation potential of the dye excited state $\phi^\circ(S^+/S^*)$ to be more negative than the conduction band flatband potential of the semiconductor, and thus:

$$\phi^\circ(S^+/S) < \phi_C + \Delta E_{0,0}/\mathcal{F} \quad (27)$$

where $\phi^\circ(S^+/S)$ is the oxidation standard potential of the dye, $\Delta E_{0,0}$ its excitation energy, ϕ_C (SC) the conduction band flatband potential, and \mathcal{F} the Faraday constant.

The redox potential for the dye can shift upon adsorption from solution due to coulombic or stronger covalent interactions with the solid substrate. This potential change can amount to several hundreds of millivolts. While n-type semiconductors cannot be used generally to measure oxidation potentials of adsorbed dye sensitizers by conventional cyclic voltammetry, reduction potential $\phi^\circ(S/S^-)$ is often more accessible. Assuming oxidation and reduction potentials of the dye ground state on the surface are linked by a constant relation:

$$\phi^\circ(S/S^-) = \phi^\circ(S^+/S) - \Delta E_{0,0}/\mathcal{F} + x \quad (28)$$

the energetic threshold for charge injection from the dye excited state into the conduction band of the solid would require the reduction potential of the adsorbed dye to be $\phi^\circ(S/S^-) < \phi_{CB} + x$, where the last term has been found for a large number of various organic sensitizer molecules to be $x = 0.35$ V [20].

The ideal sensitizer for a single-junction photovoltaic cell should absorb all light below a threshold wavelength of at least 900 nm. In addition, it should be anchored to the semiconductor oxide surface and inject electrons to the conduction band with a quantum yield of unity. Its redox potential should also be sufficiently high for it to be regenerated rapidly via electron donation from an electrolyte or a hole conductor. Finally, it should be stable enough to sustain at least 10^8 redox turnovers under illumination, corresponding to approximately 20 years of functioning under natural light in day–night cycles. The best photovoltaic performance in terms of both conversion yield and long-term stability has so far been achieved with polypyridyl complexes of ruthenium and osmium [21–24]. Sensitizers having the general struc-

Figure 9. Heterogeneous charge transfer sensitizer for molecular photovoltaic cells.

ture ML_2X_2 , where L stands for 2,2'-bipyridyl-4,4'-dicarboxylic acid (dcbpy), M for Ru(II) or Os(II), and X for halide, cyanide, thiocyanate, or water [21–24], are particularly promising. In recent years, the ruthenium complex dye *cis*- $[\text{Ru}^{\text{II}}(\text{dcbpy})_2(\text{NCS})_2]$ (Figure 9) has emerged as the model of a heterogeneous charge transfer sensitizer for molecular photovoltaic cells. Reported for the first time in 1993 [21], its performance has been unmatched since then. Only recently, a credible challenger has been found with the black dye tri(thiocyanato)-(2,2':6',2''-terpyridyl-4,4',4''-tricarboxylate)ruthenium(II) [$\equiv \text{Ru}^{\text{II}}(\text{tctpy})(\text{NCS})_3$] (Figure 9), which exhibits a better near-IR photoresponse [24].

The efficiency of *cis*- $[\text{Ru}^{\text{II}}(\text{dcbpy})_2(\text{NCS})_2]$ complex as a redox sensitizer of titanium dioxide is conferred by several important features of the molecule. Carboxylic groups carried by the ligands provide a good anchoring of the dye on the acidic surface of TiO_2 . Surface derivatization of the mesoporous oxide film is normally performed by dipping it into a solution of the dye in a 50:50 (v/v) solvent mixture of acetonitrile and *t*-butanol. A monolayer of the sensitizer is formed spontaneously. The adsorption follows a Langmuir isotherm with a binding constant $K = 5 \times 10^4 \text{ L mol}^{-1}$. The area occupied by one molecule at the anatase surface at full monolayer coverage is 1.65 nm^2 . The interaction between the carboxylic group and the oxide is of fundamental importance in determining the geometrical structure of the adsorbed dye state and influencing the electronic coupling with the Ti(3d) conduction band orbital manifold. The most likely configuration supported by IR analysis [25] involves the attachment of the dye via two of its four carboxylate groups. The carboxylate either bridges two adjacent rows of titanium ions through bidentate coordination or interacts with surface hydroxyl groups through hydrogen bonds.

Figure 10. Structural representation of a $\text{Ru}^{\text{II}}(\text{dcbpy})_2(\text{NCS})_2$ molecule adsorbed through two carboxylate groups to the (101) surface of TiO_2 .

Of the two remaining carboxylate groups, one is ionized while the other remains in the protonated form. Model studies, using the dcbpy ligand adsorbed onto single-crystal $\text{TiO}_2(110)$ rutile, investigated by means of X-ray photoelectron spectroscopy, X-ray absorption spectroscopy, and quantum chemical calculations [26], are in favor of the bridging bidentate configuration illustrated in Figure 10. The ligand is oriented at an angle of about 40° with respect to the (001) crystallographic direction. In addition to this linkage mode, calculations suggest the monodentate ester bond is also thermodynamically stable. The bidentate bonding, however, is stronger and thus would be the preferred anchoring configuration for the *cis*- $[\text{Ru}^{\text{II}}(\text{dcbpy})_2(\text{NCS})_2]$ dye on titanium dioxide.

The interfacial electron transfer events will be strongly affected by the electronic structure of the dye in the adsorbed state and the matching of the energy level between its excited state and the conduction band of the semiconductor. Generally, the optical transition of Ru complexes has metal-to-ligand charge transfer (MLCT) character. Excitation of the dye involves transfer of an electron from a metal ion d-orbital to the π^* orbital of the ligand. *cis*- $[\text{Ru}^{\text{II}}(\text{dcbpy})_2(\text{NCS})_2]$ exhibits two such transitions in the visible domain. The absorption maxima in ethanolic solution are located at 518 and 380 nm, the extinction coefficients being 1.33×10^4 and $1.3 \times 10^4 \text{ L mol}^{-1} \text{ cm}^{-1}$, respectively. The complex emits at 750 nm, the excited state lifetime being 60 ns [21].

Results from ab-initio calculation [27] of a decarboxylated *cis*-[Ru^{II}(dcbpy)₂(NCS)₂] complex show that the highest occupied molecular orbital (HOMO) level is shared by both the Ru(II) metal ion and the –N=C=S ligands. Application of photoelectron spectroscopy has confirmed that both Ru 4d and atomic orbitals centered on the –NCS groups, in particular S 3p, contribute to the HOMO of the complex [28]. In a photovoltaic cell, the oxidized dye, after electron injection to the conduction band of the oxide, should quickly be reduced by a redox species in the surrounding electrolyte. The observation that the frontier molecular orbital contains a substantial amount of 3p character from the sulfur atom of the –NCS ligand may play an important role in this process. The thiocyanate groups point in the direction of the electrolyte, which may facilitate reduction by mediators, making it particularly suitable for highly efficient solar cells.

Ab-initio calculations also show that the lowest unoccupied molecular orbital (LUMO) of the *cis*-[Ru^{II}(dcbpy)₂(NCS)₂] complex is concentrated on the π^* structure of the dcbpy ligands. Hence, absorption of visible light by the compound can be assigned to a RuNCS–bpy(π^*) charge transfer transition. Preliminary calculations also indicate that the dcbpy rings share their LUMO with the carboxylate groups, thus enhancing electronic coupling between the dye excited state and the acceptor levels manifold of the solid.

The oxidation potential and excitation energy of the fully protonated form of the dye in solution being $\phi^\circ(\text{S}^+/\text{S}) = +1.10$ V/NHE and $\Delta E_{0,0} = 1.65$ eV, respectively, the oxidation potential of the MLCT excited state of the sensitizer is established at $\phi^\circ(\text{S}^+/\text{S}^*) = -0.55$ V/NHE [21]. The flatband potential of TiO₂ in dry aprotic solvents can be as negative as $\phi_C = -1.25$ V/NHE [29, 30]. In such conditions, the conduction band of the solid would in principle be out of reach of the dye excited state and only deep localized sub-bandgap states could potentially act as acceptor levels in the injection process. Surface protonation via adsorption of the carboxylic groups results, however, in a positive shift of the flatband potential that can amount to several hundred millivolts. Moreover, complete deprotonation of the four carboxylic groups of *cis*-[Ru^{II}(dcbpy)₂(NCS)₂] was demonstrated recently to cause its oxidation potential to shift negatively by ca. 300 mV [31]. Both effects combined together with the presence of traces of H₂O render the interfacial electron transfer from the dye excited state to the conduction band of titanium dioxide thermodynamically favorable.

Dynamics of charge injection in wide-bandgap semiconductors

Photoinduced charge injection from an electronically excited molecular state into a wide continuum of acceptor levels, including the conduction band of a semiconductor, is one of the simplest photochemical surface reactions (Eq. (23)). This process is, however, rather special, in the sense that there are many channels available for the electron transfer. The reaction can choose its energetic path to yield an electron within the band of the solid, which is characterized by a variable amount of kinetic energy. The energy excess should also be carried by the dye cation S⁺, produced concomitantly, in the form of vibrational excitation. As a consequence, provided the driving force is sufficiently large compared with the nuclear reorgani-

$$k_i = \frac{4\pi^2}{h} |H|^2 \frac{1}{h\omega} n_a \quad (30)$$

In Eq. (30), the actual density of final states is approximated by the reciprocal energy level spacing $1/h\omega$ of the dye cation oscillator, multiplied by a factor $0 \leq n_a \leq 1$ accounting for the density of empty electronic states available in the solid. Above the flatband energy level, the density of acceptor states in the conduction band of a semiconductor is usually very large and the density of final states is solely determined by the density of energy levels of the dye cation ($n_a \cong 1$). Below the band edge, empty trap states are present, whose density decreases gradually at lower energies ($n_a \rightarrow 0$).

The density of accepting states $N_C(E)$ in the conduction band of a semiconductor is given by Eq. (31) [33]:

$$N_C(E) = 4\pi \left(\frac{2m_{de}^*}{h^2} \right)^{3/2} (E - E_C)^{1/2} \quad (31)$$

where E_C is the energy of the conduction band edge, and m_{de}^* the density-of-state effective mass for electrons. The latter parameter depends strongly on the material. In TiO_2 , for instance, assuming $m_{de}^* \cong m_e^* \geq 6m_e$, the calculated density of states would be at least two orders of magnitude larger than that in ZnO , for example, where $m_{de}^* \cong 0.24m_e$ [35, 36]. The density of states is also expected to be dependent upon the size of the semiconductor nanocrystallites. Strong quantum confinement indeed results in widely spaced electronic levels and therefore in a very low density of states. Although this size quantization effect would be negligible for TiO_2 where the exciton binding energy is very small, it is expected, for example, to play a significant role for ZnO particles whose diameter is smaller than ~ 10 nm.

Equation (30) can only be used when the electron transfer process takes place from a single prepared excited state of the sensitizer. In the general case, absorption of photons, whose energy $h\nu$ is larger than the electronic excitation energy $\Delta E_{0,0}$ of the dye, leads to the population of higher vibronic levels of the molecule (Eq. (32)). Relaxation of these vibrationally excited intramolecular states (Eq. (33)) and of the whole system along the classical reaction coordinate is expected to compete with the electron transfer process (Eq. (34)) [37]. In these conditions, the electronic coupling $|H|$ between the donor and the acceptor states becomes a time- and excitation wavelength-dependent function and can no longer be readily accessed [33].

Two limiting cases could be considered that would, however, let us treat in a simple way the interfacial electron transfer process as involving a single prepared excited state of the sensitizer:

- 1) Charge injection is slow enough compared with the vibrational relaxation of the dye excited state ($k_i' \ll k_r$). In this event, electron transfer would be able to take place only from the lowest excited state ($v' = 0$) (Eq. (35)), and the injection quantum yield Φ_i would be simply controlled by the kinetic competition between the electron injection (Eq. (35)) and the decay of the excited state (Eq. (36)):

$$\Phi_i = k_i / (k_i + \Sigma k_d) = k_i / (k_i + 1/\tau_f) \quad (37)$$

where τ_f is the excited-state lifetime of the sensitizer.

- 2) Charge injection is fast compared with nuclear relaxation of the excited state ($k_i' \gg k_r$). In this case, interfacial charge transfer would take place from the prepared hot vibronic level (Eq. (34)) and the quantum yield for the primary injection process would be close to unity ($\Phi_i \cong 1$). For both limiting cases, $k_i' \ll k_r$ and $k_i' \gg k_r$, relation (30) would be relevant, provided electron transfer is nonadiabatic.

When the electronic coupling of the donor and acceptor becomes sufficiently large (typically $|H| > 150 \text{ cm}^{-1} \cong 0.7kT$), the electron transfer will be increasingly adiabatic and, in the absence of solvent dynamics control, the rate constant will eventually be proportional to a nuclear vibration frequency factor ν_n . In this case the electronic coupling element is not contained in the rate expression. For other cases, where $|H|$ is small enough, the value of the coupling element is needed for a quantitative description of the electron transfer rate. There is obviously a considerable interest in the role of the electronic coupling factor, as the separation distance and anchoring geometry of the sensitizer on the surface will determine its magnitude. The Gamov expression (38) is frequently used to estimate the changes in $|H|$ with separation distance in photoinduced electron transfer where the electron donor and acceptor are fixed relative to one another:

$$|H| = |H|^0 \exp[-\beta(r - r_0)] \quad (38)$$

where the damping factor β has values ranging from 0.85 to 2.5 \AA^{-1} . Provided that other factors besides distance do not influence the electron transfer rate, Eq. (39) can be used to estimate the rate at a known separation distance r :

$$k_{et} = k_{et}^0 \exp[-\beta(r - r_0)] \quad (39)$$

where $k_{et}^0 \cong 10^{13} \text{ s}^{-1}$. Other parameters, such as spin changes, symmetry factors, and the relative orientation of both reactants, may influence the magnitude of the electronic coupling element [38].

In favorable thermodynamic conditions, where the lowest electronic excited-state energy level of the sensitizer lies above the bottom edge of the conduction band, charge injection competes kinetically with the decay of the sensitizer's excited state (Eq. (36)). Hence, for dyes that are characterized by emission lifetimes τ_f of the

order of 1 ns, interfacial electron transfer rate constants of the order of $k_i = 10^{11} \text{ s}^{-1}$ suffice to ensure high injection quantum yields. Most of the previous knowledge on bulk semiconductor–electrolyte interfacial charge transfer is derived from steady-state photocurrent measurements achieved in photoelectrochemical cells. Obtaining electron transfer rate constants from such an indirect method, however, is difficult because the photocurrent depends on many other interfacial and bulk processes.

The rapid dynamics of electron injection can be investigated by application of transient laser spectroscopy to colloidal dispersions or nanocrystalline semiconductor films. Such materials are particularly amenable to time-resolved optical studies, as they display a good transparency throughout all the visible and near-infrared (NIR) spectral domains. Moreover, they are characterized by a high solid surface area exposed to the solution, yielding high sensitizer absorbance for only monolayer dye coverage. Most of the oxide semiconductor systems that are being studied at present, namely TiO_2 , SnO_2 , and ZnO , are also of particular interest for the development of artificial photosynthetic and photovoltaic devices [39].

Earlier studies on dye-sensitized TiO_2 reported nanosecond time constants for the injection kinetics [16, 40–42]. These results were obtained indirectly from the measurement of the injection quantum yield and implicitly assumed that the interfacial electron transfer reaction was competing only with the decay of the dye excited state. Other studies were based on the same assumption but used measurements of the dye fluorescence lifetime, which provided picosecond–femtosecond time resolution [43–45]. Direct time-resolved observation of the buildup of the optical absorption due to the oxidized dye species S^+ has been employed in more recent studies [46–51]. This appears to be a more reliable way of monitoring the charge injection process as it does not require any initial assumption on the sensitizing mechanism.

Figure 12(a) shows the transient difference spectra obtained upon nanosecond laser excitation of *cis*- $[\text{Ru}^{\text{II}}(\text{dcbpy})_2(\text{NCS})_2]$ in ethanolic solution and of nanocrystalline titanium dioxide transparent films onto which the sensitizer was adsorbed. The dye is excited with 605 nm output of a laser system and the absorbance change observed immediately after the laser excitation is plotted as a function of the detection wavelength [52]. Luminescence quenching and photocurrent experiments have confirmed that 600 nm excitation of the sensitizer resulted in the formation of the charge-separated state $\text{S}^+|(\text{e}^-)\text{SC}$. The spectrum obtained upon irradiation of dye-sensitized TiO_2 displays a broad absorption feature peaking around 800 nm whose half lifetime exceeds 0.5 μs . Such a lifetime is more than one order of magnitude longer than that of the isolated dye excited state in solution. The recorded spectrum is comparable to that of the one-electron oxidation product $[\text{Ru}^{\text{III}}(\text{dcbpy})_2(\text{NCS})_2]^+$ of the complex produced by oxidative quenching of the excited state in an alcoholic solution containing methylviologen as an acceptor [47], or generated by pulse radiolysis [53]. It can be readily distinguished from the spectrum of the dye excited state obtained in solution, whose band maximum is located at 710 nm [52]. These observations demonstrate unambiguously that the transient spectral feature observed upon excitation of the sensitized semiconductor cannot be assigned to an excited state of the dye but must be attributed to the charge-separated state $\text{S}^+|(\text{e}^-)_{\text{cb}}$ resulting from interfacial charge injection, where both an LMCT transition of the $-\text{NCS}$ ligands to the $\text{Ru}(\text{III})$ metal ion center in S^+ and absorption by conduction band and/or trapped electrons contribute to the spectrum.

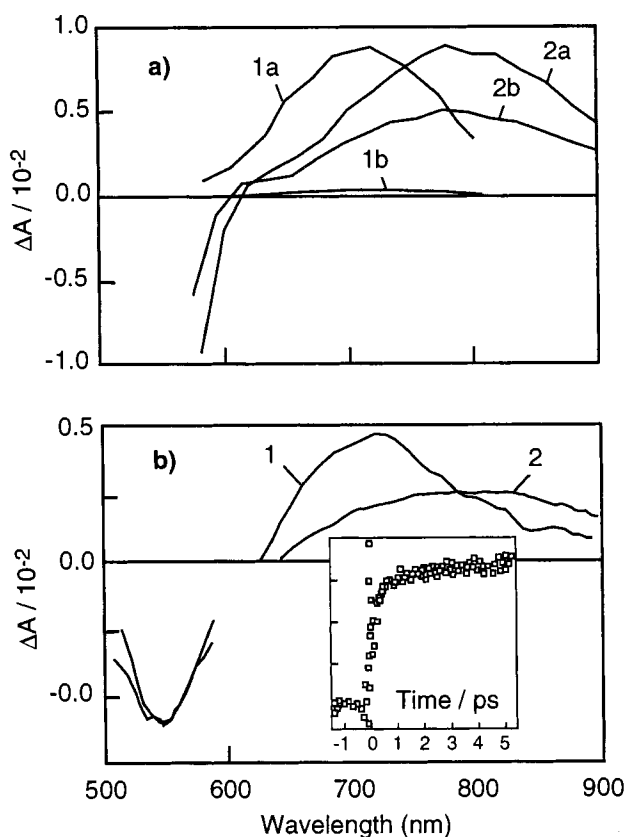

Figure 12. a) Transient absorption spectra obtained upon nanosecond pulsed laser excitation of 1) *cis*-[Ru^{II}(dcbpy)₂(NCS)₂] dye in ethanolic solution, and 2) a sensitized TiO₂ transparent film. Spectra were recorded 50 ns (1a, 2a) and 0.5 μ s (1b, 2b) after the laser excitation pulse ($\lambda = 605$ nm, 5 ns pulse duration). b) Transient absorption spectra recorded 6 ps after ultrafast laser excitation ($\lambda = 605$ nm, 150 fs pulse duration) of 1) *cis*-[Ru^{II}(dcbpy)₂(NCS)₂] dye in ethanol, and 2) a fresh sensitized titanium dioxide film. Insert, the temporal behavior of the absorbance of the latter system, measured at $\lambda = 750$ nm with sub-picosecond time resolution.

Further sub-picosecond data were collected [47]. Transient data measured for dye-sensitized TiO₂ films were compared with those obtained for control dye-coated ZrO₂ films, as the high conduction band edge of the latter material should prevent electron injection. Figure 12(b) shows the absorption difference spectra obtained at a time delay of 5 ps after 605 nm pulsed laser excitation. The spectrum obtained for the dye-sensitized zirconia films exhibits a maximum at 710 nm as observed for the *cis*-[Ru^{II}(dcbpy)₂(NCS)₂] dye in ethanolic solution and is therefore assigned to the dye MLCT excited state. On the other hand, the transient spectrum recorded for sensitized TiO₂ displays a maximum at 800 nm that is characteristic of the dye cation S⁺. In contrast to the data obtained for dye-coated ZrO₂ films, the difference spectra measured with sensitized TiO₂ exhibited some temporal evolution for time delays less than 5 ps. Typical transient absorption data at a probe wavelength of

750 nm are shown in the insert of Figure 12(b). The data show a fast ~ 100 fs instrument response limited signal growth followed by a slower kinetic phase extending to several picoseconds. A detailed multiexponential analysis of the traces obtained revealed at least three kinetic components with lifetimes of <100 fs (35 %), 1.3 ps (22 %), and 13 ps (43 %) [29, 54].

In a recent experiment [36], mid-IR spectroscopy was used to probe directly the buildup of electron concentration inside the semiconductor. Careful examination at different wavelengths and time scales yielded a complex kinetics which could be described by two exponentials with rise times of 50 ± 25 fs (>84 %) and 1.7 ± 0.5 ps (<16 %), the slower component being very sensitive to the sample condition.

The origin of such complex electron transfer kinetics is not clear yet. The participation of various electronic excited states of the Ru(II) dye sensitizer to the reaction was ruled out as no effect of the excitation wavelength could be observed. Nor was a significant difference observed in the results obtained for dyed TiO₂ films exposed to air and in propylene carbonate, thus excluding possible effects due to the solvation dynamics [54]. Direct interfacial electron transfer to various localized defect states could be associated with different electronic coupling elements and could therefore result in a wide distribution of rate constants. The occupancy of these trap states can be modulated by sweeping the Fermi level below the flatband energy upon applying an external electrical bias. Modulation of the applied potential does not appear, however, to result in any noticeable change in the injection yield and kinetics [30]. On the other hand, adsorption of potential-determining cations, such as Li⁺, that causes the flatband potential of the semiconductor to shift positively, apparently also affects the electron injection rate [55]. An acceleration factor of 8-fold was observed in particular for *cis*-[Ru^{II}(dcbpy)₂(NCS)₂]-sensitized nanocrystalline titanium dioxide in pure propylene carbonate upon addition of 0.1 M Li⁺ [30]. These observations suggest that the multiple time constants result from heterogeneities in the energetics of the nanocrystalline TiO₂ films. In addition, adsorption of dye molecules on different surface sites and with various anchoring geometries could also cause an intricate kinetic outcome [56].

The fastest kinetic phase of electron injection in *cis*-[Ru^{II}(dcbpy)₂(NCS)₂]-sensitized nanocrystalline titanium dioxide films apparently takes place in the femtosecond regime. Besides, the vibrational relaxation of the dye excited state is expected to occur typically within 0.4–1 ps ($k_r \cong 10^{12}$ s⁻¹) [57, 58]. Observed injection rate constants of the order of 10^{13} s⁻¹ certainly preclude complete thermalization of the dye excited state S* to the $v' = 0$ level prior to the reaction, and suggest that charge transfer can occur directly from hot ($v' > 0$) excited sensitizer molecules. In systems where the $v' = 0$ energy level of the electronically excited state of the dye lies below the bottom of the conduction band of the semiconductor ($n_a \rightarrow 0$), charge injection from vibrationally relaxed excited molecules of the sensitizer is either slow or unfeasible. However, if electron injection from a hot vibronic state of the dye is able to compete successfully with its nuclear relaxation ($k_i' > k_r$), charge injection should become possible for higher excitation photon energy, and an excitation wavelength dependence of the quantum yield $\Phi_i = k_i'/(k_i' + k_r)$ would be expected.

Figure 13 schematizes the energetics of the *cis*-[Ru^{II}(dcbpy)₂(NCS)₂] dye sensitizer adsorbed on various oxide semiconductors. This dye was chosen because of its

Figure 13. Energy scheme for *cis*-[Ru^{II}(dcbpy)₂(NCS)₂] dye sensitizer adsorbed on various oxide semiconductors. Molecular levels are based on the values of the oxidation potential of the complex: $\phi^0(S^+/S) = +0.86$ V/SCE and excitation energy $\Delta E_{0,0} = 1.85$ eV [21]. The flatband potentials $\phi_{fb}(SC)$ of the different solid oxides were estimated by monitoring the optical absorption at 750 nm of transparent nanocrystalline electrodes in propylene carbonate as a function of applied potential [61].

broad spectrum that should allow the excitation of hot vibronic states upon excitation by photons of energy $h\nu > \Delta E_{0,0}$. Ultrafast studies have indicated that vibrational relaxation of the analogous Ru(bpy)₃²⁺ complex dye is complete within ca. 300 fs [58, 60]. The presence of $-N=C=S$ ligands, which are characterized by a high-frequency stretching mode ($\bar{\omega} \cong 2139$ cm⁻¹) [52] is expected, however, to reduce this relaxation time to even more.

In dry propylene carbonate, the flatband energy of amorphous (a-Nb₂O₅) and crystalline niobia (c-Nb₂O₅), tantalum pentoxide (Ta₂O₅), and zirconia (ZrO₂) was found to be 0.2, 0.4, 0.7, and 1.1 eV respectively higher than that of TiO₂ [61]. As a consequence, the $v' = 0$ level of the MLCT excited state of the adsorbed dye lies below the bottom edge of the conduction band of these materials. Monitoring of the sensitizer's ground-state bleaching signal upon nanosecond laser flash photolysis of the Ru(II) complex clearly exhibited a biphasic kinetic behavior. Excited dye molecules that do not inject into the solid produce a recovery of the ground-state absorption within 15 ns. On the other hand, the dye cation S⁺, generated by the photoinduced electron transfer process, recaptures the injected electron much more slowly in the microsecond time domain [52]. Both kinetic steps, whose rate constants are two orders of magnitude apart from each other, can be easily separated. Quantitative evaluation of their respective amplitudes then allows the evaluation of the absolute injection quantum yield Φ_i at any excitation wavelength, independently of the absorption spectrum of the dye [61]. Results obtained for various

Figure 14. Dependence upon excitation photon energy $h\nu$ of electron injection quantum yield Φ_i obtained for various oxide semiconductors sensitized by $\text{cis-}[\text{Ru}^{\text{II}}(\text{dcbpy})_2(\text{NCS})_2]$.

$\text{Ru}^{\text{II}}(\text{dcbpy})_2(\text{NCS})_2$ -sensitized semiconductors show a strong excitation energy dependence of Φ_i . For $\text{c-Nb}_2\text{O}_5$ a clear wavelength dependence of the injection efficiency is observed between $\lambda = 650$ nm, the onset of injection, and $\lambda = 500$ nm, where the charge transfer quantum yield reaches a plateau value at ~ 0.75 (Figure 14). Measurements carried out in identical conditions with dye-sensitized TiO_2 gave an injection quantum yield close to unity that was independent of the excitation wavelength. On amorphous niobia, whose flatband potential is intermediate between those of TiO_2 and $\text{c-Nb}_2\text{O}_5$, the injection onset is shifted to the red by approximately 0.2 eV compared with the crystalline material. On tantalum pentoxide, the injection onset is found in the blue at $\lambda = 480$ nm. The shift of the electron injection threshold by +0.6 eV for Ta_2O_5 compared with $\text{c-Nb}_2\text{O}_5$ is larger than the energy difference measured between the positions of the respective conduction band edges of each material (0.3 eV) and should probably be related to a lower density of trap states in tantalum oxide. Finally, in accordance with the energy scheme, no charge injection was observed for $\text{cis-}[\text{Ru}^{\text{II}}(\text{dcbpy})_2(\text{NCS})_2]$ adsorbed on ZrO_2 up to an excitation energy of 2.7 eV.

The dependence of the photosensitization efficiency upon the excitation wavelength has also been observed in a photoelectrochemical cell based on TiO_2 sensitized by $\text{Fe}^{\text{II}}(\text{dcbpy})_2(\text{CN})_2$ complex [62]. The absorption band selective photon-to-current conversion efficiency measured in this case suggested that charge injection into the semiconductor is occurring via an ultra-shortlived upper excited state of the dye.

These observations of an excitation wavelength dependence of the charge injection process show that photoinduced interfacial electron transfer from a molecular excited state to a continuum of acceptor levels can take place in competition with the relaxation from upper excited levels. The rather slow growth of the injection

quantum yield above the energy onset suggests that it actually reflects the density of acceptor states in the solid that are present below the conduction band edge. In conditions where the injection quantum yield is unity ($k_i' \gg k_r$) and electron transfer takes place to the conduction band of the semiconductor ($n_a \cong 1$), the occurrence of the electron transfer process from a single prepared state $S^*(v' > 0)$ validates the simple model of Eq. (30) and makes it possible to estimate the electronic coupling matrix element $|H|$. Assuming a frequency of the dye cation oscillator $\bar{\omega}$ of 1500 cm^{-1} , a value of $|H|$ of 113 cm^{-1} ($\cong \frac{1}{2}kT$) would be calculated from the rate constant $k_i = 10^{13} \text{ s}^{-1}$ measured typically for $[\text{Ru}^{\text{II}}(\text{dcbpy})_2(\text{NCS})_2]$ -sensitized nanocrystalline TiO_2 . Although the value used for the cation vibration wavenumber $\bar{\omega}$, and therefore that determined for $|H|$, are here probably overestimated, this figure corresponds to a rather strong electronic coupling and suggests the electron injection rate could have reached the adiabatic limit.

Modulation of the injection efficiency between excited $\text{Ru}(\text{II})$ complexes and nanocrystalline TiO_2 and SnO_2 transparent films was observed upon biasing the Fermi level of the oxide electrodes [63, 64]. Applying a negative bias voltage to the film impaired the photosensitized charge injection, turning on the photoluminescence of the adsorbed dye. On the basis of these results it has been suggested that the rate of heterogeneous electron transfer depends directly upon the driving force of the reaction [64], and follows a normal Marcus-type of behavior. Alternatively, such an effect could also be rationalized by the reduction of the density of acceptor states, which are gradually populated upon raising the Fermi level of the solid. The Franck–Condon factor, which comprises parameters such as the reaction free energy ΔG^0 , the nuclear reorganization energy Λ and the temperature T , is expected to play only a negligible role in systems that are kinetically near-optimum in terms of the Marcus theory and that are characterized by a large number of acceptor states. According to Eq. (30), the rate of interfacial electron transfer for a given sensitizer is controlled only by the electronic coupling matrix element $|H|$ and the acceptor states density. The activationless nature of the charge transfer process has been experimentally confirmed by the observation of temperature-independent injection kinetics [48]. Other reported data show that, in energetically favorable conditions, the rate of electron injection is not controlled by the energetics of the sensitizer's excited state, nor by the medium reorganization, but rather by the density and occupancy of electronic states in the solid [30].

On titanium dioxide, the photoinduced charge injection process was reported to take place on time scales ranging from less than 100 fs to several microseconds, depending on the sensitizer used (Table 1). Such a variation of eight orders of magnitude can be accounted for only by very different values of the electronic coupling between the dye excited state and the acceptor orbitals at the surface of the semiconductor. Using Eq. (30), and assuming that for all systems $n_a = 1$ and a collective vibrational mode frequency of the dye oxidized state $\bar{\omega} = 1500 \text{ cm}^{-1}$, the electronic coupling matrix element can be calculated for each sensitizer. Obtained values of $|H|$ vary from 0.02 to $>160 \text{ cm}^{-1}$. Considering Eq. (38), and assuming a damping factor $\beta = 1.2 \text{ \AA}^{-1}$, this range of figures implies a difference in the electron transfer reaction distance of the order of 8 Å between the slowest and the fastest system. Various types of association of the sensitizer with the oxide surface could

^aonly the fastest kinetic component has been taken into account when multiexponential kinetics were reported, ^blinkage of most of the dye molecules onto the surface is ensured by a carboxylic or phosphonic anchoring group; in cases where such a group is lacking, adsorption occurs through purely electrostatic interactions, ^c $\text{Fe}(\text{CN})_6^{4-}$ and alizarin form charge transfer (CT) surface complexes on TiO_2 that are the relevant chromophores in the photosensitization process, ^delectronic matrix elements $|H|$ coupling dye excited states with the acceptor states of the semiconductor were calculated with Eq. (30), assuming for all systems $n_a = 1$ and $\bar{\omega} = 1500 \text{ cm}^{-1}$.

explain such a difference. Adsorption through electrostatic interaction is clearly insufficient. In aqueous medium, water molecules adsorbed on TiO_2 can act as spacers and force the dye sensitizer to stay several ångströms apart from the solid. Moreover, in the case of the symmetric $\text{Ru}(\text{bpy})_3^{2+}$ complex, the LUMO of the dye is delocalized over all three ligands, thus considerably increasing the average separation distance for interfacial electron transfer. Strong electronic coupling between the π^* molecular orbital of the dye excited state and the empty $\text{Ti}(\text{IV})$ 3d orbital manifold of the semiconductor is achieved by directly linking the sensitizer's moiety that carries the lowest-energy π^* orbital to the surface. Carboxylic and phosphonic anchoring groups are quite good at coupling dye-sensitizers onto the surface of TiO_2 . Charge injection rate constants obtained with such systems appear hardly to be dependent on the type of chromophore used, as they all establish at ca. $k_i = 10^{13} \text{ s}^{-1}$, a value which is probably close to the adiabatic limit.

Recapture of the injected electron

Figure 15 schematizes the energetics and dynamics of processes that take place after charge injection from a molecular excited state to the acceptor levels of a semiconductor. Thermalization and trapping of hot injected carriers is known to occur typically with a rate constant $k_{\text{th}} \cong 10^{13} \text{ s}^{-1}$ [69–71]. Reverse transfer of a hot

Figure 15. Energetics of the charge recombination following electron injection (k_i) from a dye excited state S^* into the conduction band of a semiconductor. Thermalization and/or trapping of injected electrons (k_{th}) takes place prior to the interfacial electron back transfer to the dye oxidized state S^+ (k_b). The reaction free energy associated to the latter process depends upon the population of the electronic states in the solid and can be distributed over a broad range of values. Numerical potential data shown are those of the *cis*-[Ru^{II}(dcbpy)₂(NCS)₂]/TiO₂ system.

electron (k_{-i}) is therefore generally prevented. The kinetics of back electron transfer from the conduction band to the oxidized dye follow a multiexponential time law, occurring on a microsecond-to-millisecond time scale. Two reasons are suggested for the relatively slow rate of the recapture of the injected electron:

- 1) While electron injection is kinetically near optimum, the high exoergicity of the back electron transfer can make the system lie deep in the inverted Marcus region, where the rate of the charge transfer process is expected to decrease with increasing driving force.
- 2) Alternatively, the dynamics of trapping and detrapping of electrons localized in intra-bandgap states can control the overall reaction kinetics, which would not depend upon the sole interfacial electron transfer rate.

Efficient dye sensitizers of oxide semiconductors are generally characterized by an oxidation potential of their excited state $\phi^\circ(S^+/S^*)$ that is close to the conduction band flatband potential ϕ_b of the solid. As a consequence, the free energy ΔG_b^0 of the back electron transfer can be as negative as -1 to -2 eV, depending on the potential assumed for free and/or trapped electrons involved in the reaction. The total reorganization energy associated with the heterogeneous charge transfer process is typically of the order of 0.5 eV, and is therefore smaller than the reaction

driving force $\Lambda < -\Delta G_b^0$. In terms of current electron transfer theory, this situation, depicted in Figure 15, corresponds to an inverted kinetic region.

For a nonadiabatic process the ET rate constant is generally expressed by Eq. (29). Within the classical limit where the energy of the vibrational modes associated with the activated complex formation is small ($h\nu \ll kT$):

$$FC = \sqrt{2\pi\Lambda kT} \exp(-\Delta G^\ddagger/kT) \quad (40)$$

and

$$\Delta G^\ddagger = (\Delta G^0 + \Lambda)^2/4\Lambda \quad (41)$$

where ΔG^\ddagger is the reaction activation energy. However, this classical expression is not generally adequate to describe the kinetics of electron transfer within the inverted region. Introducing a quantum modification of the Franck–Condon factor by assuming a single collective high-frequency vibrational mode ($h\nu > kT$) yields:

$$FC = \sqrt{2\pi\Lambda_o kT} \exp\left(-\frac{\Lambda_i}{h\nu}\right) \sum_{w=0}^{\infty} \frac{1}{w!} \left(\frac{\Lambda_i}{h\nu}\right)^w \exp\left(-\frac{(\Delta G^0 + w h\nu + \Lambda_o)^2}{4\Lambda_o kT}\right) \quad (42)$$

where Λ_i and Λ_o are the high-frequency mode (inner sphere) and low-frequency mode (inner- and outer-sphere) terms of the reorganization energy, respectively. The quantum treatment of high-frequency vibrational modes has a marked effect in the inverted Marcus region. The large Franck–Condon coupling that generally characterizes the inverted region renders nuclear tunneling a dominant process. The first consequence of this effect is a drastic decrease in the dependence of the electron transfer rate upon its energetics. Nuclear tunneling underneath the nuclear reorganization barrier also means that the electron transfer process in these conditions becomes activationless. As a second consequence, it is therefore expected that the temperature dependence of the electron transfer kinetics vanishes.

In accord with the experimental findings that the charge recombination process exhibits inverted-region kinetic behavior [72–75] and the predictions of the semi-classical model above, pseudo-activationless kinetics were indeed observed. The dynamics of the electron back transfer from the conduction band of TiO₂ nanoparticles to the cations of various organic sensitizers was shown to be essentially insensitive to temperature [75]. The temperature and medium dependence of the kinetics of the back electron transfer process taking place from the conduction band of mesoporous TiO₂ to the oxidized form of the adsorbed *cis*-[Ru^{II}(dcbpy)₂(NCS)₂] dye-sensitizer was also investigated [76, 77]. As expected from the thermodynamics of the process ($\Delta G^\circ \cong -1.75$ eV in ethanol), which should make the reaction lie deep in the inverted region, the effect of the temperature on the reaction rate was very weak. A decrease in the rate constant by a factor of less than 2 was observed when the temperature was varied from 300 K down to 100 K. This and the fact that hardly any medium dependence of the electron transfer rate could be observed

suggested that the Franck–Condon barrier to electron transfer is dominated by high-frequency modes which lead to its rate of crossing being mainly controlled by nuclear tunneling.

The insignificant role played by the Franck–Condon factor implies the electronic coupling dictates to a large extent the kinetics of the charge transfer process. Fitting of experimental temperature dependence data by Eqs. (29) and (42) yielded values of the electronic coupling matrix element $|H|$ of the order of only a few cm^{-1} [75]. This electronic coupling is fairly weak compared with that of the charge injection, where $|H|$ was found for the same sensitizer to be one or two orders of magnitude larger. This difference could be explained by the configuration of the sensitizer molecules in the adsorbed state. In efficient systems, forward electron transfer is favored by directly anchoring the sensitizer's moiety that carries the LUMO of the dye to the surface. In molecules that possess a large transient dipole moment, charge recombination requires that the electron must be transferred from the semiconductor to the oxidized center over a longer distance. This effect is particularly evident for Ru(II) complexes such as *cis*-[Ru^{II}(dcbpy)₂(NCS)₂]. Electron injection into TiO₂ takes place from the carboxylated bipyridyl ligands that are linked to the oxide surface and carry the lowest π^* orbital. The distance separating the center of the π^* system in the sensitizer's excited state and the first layer of Ti(IV) ions in the solid is approximately 5.5 Å. The reverse reaction, however, involves an electron transfer from the semiconductor to the Ru(III) center of the oxidized state, about 8 Å apart. According to the Gamov expression (Eq. (38)), and assuming $\beta = 1.2 \text{ Å}^{-1}$, a difference of 2.5 Å in the ET distance would imply a variation of the value of the electronic coupling by a factor of 20, in good agreement with experimental data. For systems that do not apparently benefit from this favorable effect, charge recombination was reported to occur in the sub-nanosecond time scale [49, 50, 78]. Logically, the value of the electronic coupling in these cases was estimated to be of the same order of magnitude ($|H| \cong 50\text{--}100 \text{ cm}^{-1}$) as that of the electron injection process [50, 79].

Whether charge transfer occurring through the solid/liquid interface proceeds directly from free electrons in the conduction band or is mediated by surface states is an important clue in the understanding of the mechanism and kinetics of the back electron transfer reaction. In principle, a distribution of energetically different traps for electrons could be responsible for a non-single-exponential recombination rate. Multiexponential kinetics of back electron transfer processes was indeed reported in several recent publications. Durrant and co-workers have presented some new data on this issue, showing the reaction to be strongly dependent on applied potential and electrolyte composition [80]. In agreement with the conclusions reached by Lian and co-workers [66, 81], these observations show that kinetics of charge recombination between electrons injected into nanocrystalline TiO₂ films and adsorbed dye cations are strongly dependent upon occupancy and energetics of the electronic states in the solid. They also suggest that the back electron transfer dynamics is controlled by electron transport between energetically distributed trap sites within the oxide nanoparticles [82]. This may be of relevance for the performance of the cell and should be considered in the modeling of the electrical performance together

with the reaction between the electrolyte mediator and conduction band electrons [83].

1.4.4 Charge Separation in Molecular Photovoltaic Devices

Upon irradiation, redox dye photosensitizers adsorbed on the surface of wide-bandgap metal oxide semiconductors readily inject an electron in the conduction band of the solid. While charge injection has been found for numerous efficient systems to occur in the femtosecond time frame, the electron back transfer takes place much more slowly, typically in the microsecond–millisecond domain. This charge recombination process can be intercepted by reaction of a reducing mediator *M* with the oxidized dye (Eq. (43)). The overall efficiency of the light-induced charge separation then depends upon the kinetic competition between back electron transfer and dye regeneration processes.

Photovoltaic cells based on the sensitization of mesoporous titanium dioxide by Ru(II) complex dyes in conjunction with the I_3^-/I^- redox couple as a mediator have proved very efficient at exploiting this principle. In such systems, the ionic mediator travels back and forth by diffusion from the working electrode to the counterelectrode, to shuttle to the sensitizer the electrons that have gone through the electrical circuit [18, 21, 84]. Recently, solid-state devices have been described where the liquid electrolyte present in the pores of the nanocrystalline oxide film is replaced by a large-bandgap p-type semiconductor acting as a hole-transport medium [85–88].

Interception of dye cations by a redox mediator

The interception of the oxidized dye by the electron donor in the electrolyte, i.e., iodide, is crucial for obtaining good conversion yields and high cycle lifetime of the sensitizer. For *cis*-[Ru^{II}(dcbpy)₂(NCS)₂] dye, time-resolved laser experiments have shown the interception to take place within about 10 ns under the conditions applied in the solar cell. The S^+/S couple shows reversible behavior in different organic solvents, the standard redox potential in acetonitrile being $\phi^o = 0.83$ V/SCE. The lower limit of 1 s can be derived for the lifetime of the oxidized dye from cyclic voltammetry. This means that interception is 10^8 times faster than intrinsic degradation of the oxidized sensitizer, explaining the fact that *cis*-[Ru^{II}(dcbpy)₂(NCS)₂] can sustain 100 million turnovers in continuous solar cell operation without loss of performance. Lack of adequate conditions for rapid regeneration of the dye leads to dye degradation.

The I_3^-/I^- redox couple has been found to be particularly suited for dye-sensitized photoelectrochemical solar cells based on nanocrystalline TiO₂, as it rapidly regenerates the sensitizer (Eq. (44)) and ferries charges between the two electrodes.

In these devices no other known redox couple works nearly as well. Although in solution I^- is capable of quenching reductively the excited state of many dyes (Eq. (25)), on a semiconductor surface such as SnO_2 and TiO_2 , the iodide quenching is not able to compete kinetically with the ultrafast charge injection [89].

The detailed mechanism of the two-electron transfer dye regeneration reaction (Eq. (44)) has not been fully elucidated and many factors appear to influence its rate [23, 84]. The following one-electron transfer reactions can in principle take place on the surface of the oxide and account globally for the oxidation of iodide to triiodide [23, 90]:

Oxidation of iodide to the $I_2^{\bullet -}$ radical is thermodynamically more favorable than the reaction leading to the iodine atom [91]. Thus, reaction (47) is favored over reaction (45), provided that (I^\bullet, I^-) or (S^+, I^-) ion pairs are present in a significant amount [23, 90].

The kinetics of the oxidation of iodide by the oxidized state of *cis*-[$Ru^{II}(dcbpy)_2 \cdot (NCS)_2$] sensitizer adsorbed on nanocrystalline TiO_2 films was measured by transient laser spectroscopy [92]. Figure 16 shows the transient absorption kinetics recorded in propylene carbonate with various electrolytes added. In all cases, the recovery of the ground-state absorption of the dye, after the fast electron injection into the solid, does not follow a simple kinetic law. In the absence of any electrolyte (trace a), the time needed to reach half of the initial absorbance ($t_{1/2}$) through back electron transfer is 2 μs . Total recovery of the initial absorption, however, requires several hundreds of microseconds to milliseconds. Traces b, c, and d were recorded after addition of a common concentration of 0.1 M of iodide in the form of tetrabutylammonium (TBA^+), Li^+ , and Mg^{2+} salts, respectively. Addition of the electrolyte in all three cases led to a considerable acceleration of the dye regeneration with $t_{1/2} < 200$ ns and complete suppression of the slow kinetic tail.

The rate of the reaction leading to the regeneration of the dye ground state was found to depend strongly on the nature and concentration of cations present in the solution. Small cations able to specifically adsorb onto the oxide surface, such as Li^+ and Mg^{2+} , were found to favor the fast oxidation of iodide by the oxidized state of the sensitizer. A sudden acceleration of the electron transfer process was observed at a critical cation concentration (see insert of Figure 16). Electrophoretic measurements showed that this concentration corresponds to the reversal of the titanium dioxide particle surface charge from negative to positive upon adsorption of ζ -potential-determining species. This observation was interpreted in terms of a

Figure 16. Time course of the transient absorbance changes measured upon laser excitation of *cis*-[Ru^{II}(dcbpy)₂(NCS)₂] dye adsorbed on nanocrystalline TiO₂ films. Bleaching signals were measured at $\lambda = 520$ nm in anhydrous propylene carbonate, a) without electrolyte, and in the presence of b) 0.1 M TBAI, c) 0.1 M LiI, and d) 0.05 M MgI₂. Insert, dependence of the half-lifetime $t_{1/2}$ of the dye ground-state absorbance recovery upon the concentration of Li⁺ cations. Iodide concentration of [I⁻] = 0.1 M was kept constant while $pLi^+ \equiv -\log[Li^+]$ was varied.

change in the reaction mechanism characterized by different rate constants. The slower reaction path, which does not require the iodide anions to be adsorbed onto the surface, was attributed to the thermodynamically unfavorable oxidation of I⁻ to an iodine atom (Eq. (45)). Alternatively, the encounter of an (S⁺, I⁻) complex with a second iodide anion could yield I₂^{-•} radicals directly as a product of the electron transfer process (Eq. (49)).

These reactions should be prevalent as long as the solid surface is negatively charged. When the surface charge is reversed to positive upon adsorption of the cations, a faster mechanism becomes predominant. Because it requires a high local concentration of I⁻ on the surface of TiO₂, the latter was suggested to be due to the thermodynamically more favorable oxidation of I⁻ to I₂^{-•}, which involves prior formation of (I⁻, I⁻) ion pairs on the surface (Eq. (50)).

Apart from recapture of the injected electrons by the oxidized dye, there is an additional loss channel in the nanocrystalline dye-sensitized cell which involves reduction of triiodide ions in the electrolyte present within the mesoporous network:

The back electron transfer reaction between conduction-band electrons and I_3^- (Eq. (51)) is the ultimate fate of photoinjected carriers. This reaction can be directly followed by measuring the dark current of the photovoltaic cell. The latter should be kept at a minimal level as it determines the photovoltage and, hence, the overall conversion efficiency of the device [93–95]. On mesoporous TiO_2 electrodes sensitized by $\text{cis-Ru}^{\text{II}}(\text{dcbpy})_2(\text{NCS})_2$, the rate of the back reaction of injected electrons with I_3^- was measured from intensity-modulated experiments and was observed to be second order in the electron density, with $k = 8.4 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$ [95]. As for the direct recombination processes discussed above that also imply the reaction of conduction-band and trapped electrons with acceptor molecules at the surface, the rate of charge transfer is expected to depend strongly upon the distribution and occupancy of intra-bandgap states in the semiconductor, and therefore upon the light intensity, the applied potential bias, and the nature and concentration of adsorbates.

Charge carrier percolation through mesoporous solid films

The migration of electrons within the TiO_2 conduction band to the current collector involves charge carrier percolation over the mesoscopic particle network. This important process which leads to nearly quantitative collection of injected electrons is at present attracting a great deal of attention [82, 96–99]. The mesoporous electrode is very different from a compact semiconducting layer because

- 1) the nanocrystalline film possesses only a very low inherent conductivity,
- 2) a space-charge layer is unable to establish within minute individual particles that are smaller than the Debye length, and
- 3) the oxide particles and the pores filled by the electrolyte form interpenetrating networks whose phase boundaries produce a junction of huge contact area.

In an approach to rationalizing the transport phenomena, mesoporous films may be viewed as an ensemble of individual nanoparticles through which electrons can percolate by hopping from one crystallite to the next, rather than regarding them as perforated compact electrodes [39].

A first attempt to model carrier transport in nanocrystalline TiO_2 films suggested diffusion to be the operative mechanism [96]. It turned out, however, to be erroneous to describe the electron motion by a single value of the diffusion coefficient. The transport phenomenon is complex as it involves trapping and detrapping of charges. The traps have various depths, leading to a distribution of trapping and detrapping times. Which type of trap the electron experiences during its random walk through the oxide film depends on its quasi-Fermi level under illumination, i.e., on the light intensity [97]. At low light levels, deep traps participate in the electron motion with a correspondingly low diffusion coefficient D_{e-} , and slow motion is expected. Increasing light intensity ends up in the filling of deeper trap states under steady-state conditions. The transport in this case is faster since it involves only shallow traps, resulting in a higher value for D_{e-} . The central importance of trap states in these systems has recently been discussed by Nelson [82], who applied a dispersive transport model based on the continuous-time random-walk theory of Scher and Montroll [100].

Another currently debated issue concerns space charge control of the photocurrent. It is generally assumed that the negative charge of the moving electron is efficiently screened by cations in the electrical double layer surrounding the semiconductor nanoparticles, making it move with its image charge as an essentially neutral species. There is evidence, however, that the charge compensation on the electrolyte side of the junction can lag behind the electron movement in the solid network. This effect is particularly important in ion-paired organic electrolytes when high photocurrents are drawn. Therefore, it was observed in photocurrent transient measurements that the photocurrent response times became longer with decreasing electrolyte concentration [101]. As well, the calculated value of the effective diffusion coefficient of carriers in the oxide semiconductor $D_{e^-} = 1.5 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$, is several orders of magnitude smaller than that in the bulk crystalline material and strikingly similar to the diffusion coefficient of ions in the solution. A description of the coupled electron-ion motion [83] and a quantitative model of the mass transport by the electrolyte in mesoporous systems [102] have been proposed, albeit employing a constant value for the electron diffusion coefficient.

Simple calculation shows that the steady-state carrier concentration in full sunlight corresponds to approximately one electron per TiO_2 particle [103]. However, using this value together with $D_{e^-} = 1.5 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$ ends up in a resistance for the illuminated nanocrystalline film which is at least a thousand times higher than the experimentally measured value. This discrepancy may be explained by a Mott transition occurring during the photodoping in the anatase particles that results in a large increase in their conductivity [104]. Clearly, a central question remains, which is how, in the dye-sensitized liquid-junction solar cell, an initially very poorly conducting network of TiO_2 nanoparticles can attain the excellent photocurrent-voltage characteristics presented below in Section 1.4.6.

Charge separation across a solid-state heterojunction

In dye-sensitized photovoltaic cells, practical advantages may be gained by the replacement of the liquid electrolyte with a solid charge transport medium. Inorganic p-type semiconductors, such as CuI [86] and CuSCN [88], and organic hole conductors [85, 105, 106] have been proposed in this regard. Recently, the use of 2,2',7,7'-tetrakis(*N,N*-di-*p*-methoxyphenylamine)-9,9'-spirobifluorene (spiro-MeOTAD) to constitute an amorphous hole-transmitting material, in conjunction with a mesoporous TiO_2 film sensitized by *cis*- $[\text{Ru}^{\text{II}}(\text{dcbpy})_2(\text{NCS})_2]$, made it possible to build a solid-state dye-sensitized solar cell with high photon-to-electron conversion efficiencies [85].

Figure 17 shows an energetic scheme for the electron transfer processes taking place at the dye-sensitized heterojunction of such a device. Electron injection from the sensitizer's excited state into the conduction band of TiO_2 is followed by regeneration of the dye by hole injection into the hole transport material (HTM). Conduction-band electrons in the metal oxide, as well as holes in the organic medium, are then transported by electronic conduction to the anode and the cathode, respectively. Pulsed picosecond laser photolysis has shown that the hole injection from the oxidized dye sensitizer $[\text{Ru}^{\text{III}}(\text{dcbpy})_2(\text{NCS})_2]^+$ into the spiro-MeOTAD

Figure 17. Energetic scheme of electron transfer processes taking place in a dye-sensitized heterojunction photovoltaic cell. Also shown is the structure of the spiro-MeOTAD molecule that constitutes an efficient organic hole transport material (HTM).

hole conductor proceeds over a broad time ranging from <3 ps to >1 ns [107]. This wide time scale was attributed to a statistical distribution of the dye–hole conductor distances, and suggested that the dye was not perfectly and uniformly contacted by spiro-MeOTAD molecules.

1.4.5 Charge Separation in Nanocrystalline Heterotriads

Charge separation resulting from light absorption by molecular chromophores has been extensively studied along two parallel routes. On the one hand, numerous molecular assemblies of donors (D), chromophores (S), and acceptors (A) in many variations have been synthesized, forming dyads, triads, tetrads, or even pentads, to achieve charge separation in solution or in monolayers. On the other hand, charge separation at chromophore–semiconductor interfaces (heterodyad S–A) exploited on films of nanocrystalline metal oxides has allowed the development of dye-sensitized nanocrystalline solar cells. Combining the intramolecular with the interfacial light-induced charge separation strategies is expected to increase the light-to-electricity conversion yield of the photovoltaic systems.

The maximum voltage delivered by the dye-sensitized solar cell corresponds to the difference between the potential corresponding to the quasi-Fermi energy

Figure 18. Electron fluxes for charge separation and recombination processes in a heterodyad (top) and heterotriad (bottom), in the presence of a redox mediator in solution, under open-circuit conditions. In the heterodyad, the injected electrons can either recombine with the oxidized sensitizer S^+ (I_b) or reduce the oxidized mediator M^+ (I_M). S^+ is reduced either by the conduction-band electrons or by the redox mediator M (I_i). In the heterotriad, the electron transfer from the linked donor D to S^+ is much faster than the recombination. The new recombination process occurs at $k'_b < k_b$ due to the larger distance.

level of the electrons in the semiconductor $\phi_F = E_{F,n}^*/\mathcal{F}$ and the redox potential $\phi(M^+/M)$ of the mediator in solution. A higher cell voltage can hence be obtained by lowering the quasi-Fermi potential which depends on the electron concentration in the conduction band of the illuminated sensitized semiconductor. This concentration relaxes to a steady state where the electron injection I_{inj} flux equals the electron escape flux (Figure 18). The escape flux is composed of two contributions: the electron-sensitizer recombination flux I_b (Eq. (52)) and the electron leak to the mediator in the contacting electrolyte I_M (Eq. (53)).

Lowering the quasi-Fermi potential by reducing the former flux requires a lengthening of the lifetime of the charge-separated state $S^+|(e^-_{cb})TiO_2$, a goal which can be reached by removing the hole on S^+ away from the semiconductor surface. This was achieved by replacing the simple chromophoric sensitizer S by a dyad sensitizer $S-D$ in which D is an electron donor possessing a redox potential lower than that of the sensitizer but higher than that of the redox mediator. Consequently, after electron injection, the hole will be transferred from S^+ to D (reaction (54)). The recombination according to Eq. (55) is expected to be slower than the direct recombination (Eq. (52)), because of the exponential decay of the electron transfer rate $k_{et}(r)$ with the distance r , according to Gamov's expression (39). The whole system

D-S[TiO₂] constituted by the dyad adsorbed on the semiconductor, considered as an acceptor, will be referred to as a *heterotriad*.

The quantitative influence of the different rates of electron transfers on the photopotential ϕ_F of the illuminated electrode was established according to the following model. In a heterodyad S[TiO₂] in open circuit (Figure 18, top), the electrons injected into the TiO₂ conduction band at the flux I_{inj} can either recombine with the oxidized sensitizer with the pseudo first-order rate constant k_b or reduce the oxidized redox mediator M^+ in solution with the second-order rate constant k_M . The steady-state electron density n in the semiconductor is thus given by Eq. (56). The quasi-Fermi level $E_{F,n}^*$ of the semiconductor is varying with the electron density according to Eq. (57), where E_C is the conduction band level and N_c is the effective density of states in the conduction band, a constant value for a given material at a given temperature [108]. The corresponding photopotential ϕ_F of the electrode is obtained by division by the Faraday constant \mathcal{F} (Eq. (58)). Combining Eqs. (57) and (58) affords the photopotential as a function of the kinetic parameters (Eq. (59)). In a heterotriad D-S[TiO₂] (Figure 18, bottom), the quenching of the oxidized dye by the linked donor is by far the fastest process ($k_q \gg k'_b$; see examples below). I_b is therefore negligible and the relevant fluxes for the determination of $\Delta\phi_F'$ are I_M which is independent of the sensitizer, I'_{inj} , and the recombination flux I'_b with the oxidized donor. The open-circuit photopotential difference $\Delta\phi_F$ between the two systems is then expressed by Eq. (60), which can be further simplified if $I'_{inj} = I_{inj}$; this can be considered true if the chromophore is the same in the heterodyad and in the heterotriad.

$$n = I_{inj} / (k_b + k_M[M^+]) \quad (56)$$

$$E_{F,n}^* = E_C - kT \ln(N_c/n) \quad (57)$$

$$\phi_F = \phi_c - (kT/\mathcal{F}) \ln(N_c/n) \quad (58)$$

$$\phi_F = \phi_c - (kT/\mathcal{F}) \ln(N_c - (k_b + k_M[M^+])/I_{inj}) \quad (59)$$

$$\Delta\phi_F = (kT/\mathcal{F}) \ln(k_b I'_{inj} / k'_b I_{inj}) \quad (60)$$

An improved solar cell voltage can also be achieved by raising the redox potential of the mediator. The substitution of the heterotriad for the heterodyad is in that case an advantage, too. In fact, the higher redox potential of the (M^+/M) couple results in a reduced driving force for the regeneration of the dye ($S^+ + M \rightarrow S + M^+$) which will be accompanied, in the normal Marcus region, by a reduced rate. If this rate decreases, the competitive recombination flux increases, unless, again, the lifetime of the charge-separated state is prolonged by fast transfer of the hole to a linked donor.

Argazzi et al. followed that strategy to elaborate a nanocrystalline solar cell which incorporates a molecular dyad (**H1**) based on ruthenium bipyridine as a sensitizer and phenothiazine as a donor (Figure 19) [109].

In compound **H1**, the respective redox potentials of the S ($Ru^{III/II}$) and D ($PTZ^{+/0}$) moieties are 1.33 and 0.97 V/NHE, giving a 0.36 V driving force for the charge transfer. In the model compound where the donor is absent, charge recombination

Figure 19. Molecular dyad based on ruthenium bipyridine and phenothiazine [109].

was determined by transient laser spectroscopy to follow a biexponential process, with the kinetic components $k_{b1} = 8.5 \times 10^6 \text{ s}^{-1}$ (77 %) and $k_{b2} = 5.1 \times 10^5 \text{ s}^{-1}$ (23 %). In heterotriad **H1**|TiO₂, electron transfer from the phenothiazine moiety to the oxidized sensitizer took place within the laser pulse (<30 ns) while the charge recombination occurred at the rate $k'_b = 3.6 \times 10^3 \text{ s}^{-1}$, which means a decrease by a factor of 2000 compared with the heterodyad, and a half-lifetime of the charge-separated state of 300 μs . According to Eq. (60), the photopotential of the heterotriad should be 200 mV higher than for the heterodyad. A difference of 175 mV was measured in the absence of redox mediator. The former system still afforded a 100 mV-higher open-circuit voltage than the latter in a cell where the I_3^-/I^- couple was present.

Bonhôte et al. investigated three systems based on ruthenium–terpyridine–phosphonate as sensitizer and triarylamine as donors [110]. The excited form of the considered sensitizer was reported to inject electrons efficiently into TiO₂ [111, 112], while triarylamine are known to form very stable cation radicals [113]. In the two heterotriads **H2**|TiO₂ and **H3**|TiO₂ (Figure 20), the donor and the sensitizer are covalently linked at different distances while the co-adsorbed phosphonated triarylamine **A1** and ruthenium terpyridine sensitizer **H4**, or **H5** constitute *bimolecular* heterotriads. The redox potentials of the different constituents of the heterotriads are given in Figure 20. The driving forces for the $\text{D} \rightarrow \text{S}^+$ charge transfer were 0.55 V for **H2**, 0.65 V for **H3**, and 0.56 V for **A1** + **H5**.

Resonance Raman spectroscopy indicated that in the excited assemblies **H3***|TiO₂ and (**A1** + **H5***)|TiO₂, one electron is promoted from the metal center to the terpyridine ligand linked to the semiconductor, whereas in the system **H2***|TiO₂ the excited electron is located on the ligand linked to the donor. The quantum yield of the charge separation reaction (54) was found to be close to unity for the two former assemblies, but only 60 % for the latter one. In all three cases, the electron injection was very fast (<1 ns) and the hole transfer to the donor was fast (10–20 ns). The half-lifetime of the charge-separated state was 3 μs for (**A1**⁺ + **H5**)|(e[−]_{cb})TiO₂, as in the model system **H5**⁺|(e[−]_{cb})TiO₂; it was 30 μs in **H2**⁺|(e[−]_{cb})TiO₂ and 300 μs in **H3**⁺|(e[−]_{cb})TiO₂, as with **H1**⁺|(e[−]_{cb})TiO₂.

Figure 20. Distances, energy levels and electron transfer half-lives in the heterotriads **H2/TiO₂**, **H3/TiO₂** and **H5+A1/TiO₂**. The distances were calculated by molecular mechanics using CAChe software, assuming a perpendicular arrangement of the molecules on the surface. The energy levels are those obtained and calculated by electrochemistry as well as by absorption and emission spectroscopy. The half-lifetimes reported for the electron transfer processes were obtained by laser flash photolysis. The value of 3 μs for the S⁺[(e⁻_{cb})/TiO₂ → S/TiO₂ recombination was obtained with the heterodiyad **H5/TiO₂**.

The differences in the recombination rates of the different heterotriads can be correlated with the mean distance separating the amine from the surface of the oxide. Perpendicular attachment of the molecules on the surface would imply D–TiO₂ distances of 12, 18, and 24 Å for the heterotriads (**A1**⁺ + **H5**)/TiO₂, **H2**/TiO₂, and **H3**/TiO₂, respectively (Figure 20). Assuming a typical damping factor $\beta = 1.2 \text{ Å}^{-1}$ for “through-space” electronic coupling between conduction band electrons and D⁺, a decrease of the recombination rate by one order of magnitude is expected to correspond to an increase in the mean electron transfer distance by 1.9 Å. The discrepancy between that value and the 6 Å distance difference expected from perpendicular anchoring can be explained by the fact that it is very likely that a large portion of adsorbed molecules adopt a tilted conformation on the surface, leading to a broad distribution of distances for the charge recombination, and hence to a complex kinetic behavior. In fact, attempts to fit the observed temporal curves demonstrated that they are multiphasic, certainly because the adsorption geometry of the molecules is not fixed. This geometry is likely to be dependent on the surface coverage. In a compact monolayer, perpendicular anchoring should be favored, whereas molecules widely dispersed on the surface should be freer to lean over. It was indeed observed for all three heterotriads that the rate of the recombination depends drastically on the surface concentration. At 50 % surface coverage, upon irradiation by a laser pulse of fixed energy, a 50 % reduction of the number of charge-separated pairs is expected. Considering a second-order kinetic law, the rate of recombination is expected to decrease accordingly. It was observed on the contrary that the slowest kinetic components measured for **H3**/TiO₂ at surface saturation disappeared under partial coverage conditions, while the half-lifetime of the charge-separated state $\tau_{1/2}$ was reduced by more than one order of magnitude. An effect of the same amplitude was observed with heterotriads **H2**/TiO₂ and (**A1** + **H5**)/TiO₂. Heterotriad **H3**/TiO₂ represents clearly the most promising system of the series for long-lived charge separation. In an attempt to increase further the lifetime of **H3**⁺|(e[−]_{cb})TiO₂ state, the photodynamics was studied in the ambient-temperature liquid salt 1-ethyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide [114], which was shown to behave at the molecular scale like a solvent of low dielectric constant ($\epsilon \approx 10$), where the medium reorganization energy should be minimized. The charge recombination was indeed slowed down significantly, with a twice as long $\tau_{1/2}$ as in propylene carbonate. A very long tail in the kinetic curve, accounting for a few percent of the initial absorbance, was even found to extend up to several hundreds of milliseconds ($\tau_{1/4} = 5 \text{ ms}$, $\tau_{1/8} = 120 \text{ ms}$). Careful degassing of the molten salt did not affect this long-time kinetic phase, indicating that removal of the conduction band electrons by molecular oxygen was not competing with the charge recombination.

Under full sun illumination (AM 1.5) in propylene carbonate, heterotriad **H2**/TiO₂ gave a 82 mV higher photopotential than **H5**/TiO₂ of which only 58 mV can be accounted for by the 10-fold reduced recombination rate. Another contribution of 10 mV is expected from the 50 % higher injection flux I_{inj} of the former system, due to the wider absorption spectrum. In spite of a 100-fold lower recombination rate compared with **H5**/TiO₂, expected to yield a 116 mV gain, the heterotriad **H3**/TiO₂ gave the lowest photopotential of the series. This observation must

be related to a supplementary contribution to I_b represented by the short-circuiting pathway constituted by the lateral charge percolation from triarylamine to triarylamine and finally to the SnO_2 , as shown by the electrochromism of H3|TiO_2 . This was confirmed by the observation that the quantum yield of the whole charge separation process increased when **H3** was diluted on the surface by non-electroactive molecules.

In a regenerative solar cell, with the I_3^-/I^- redox couple, the open-circuit photovoltage of H2|TiO_2 was now 139 mV higher than that of H5|TiO_2 . This increased difference can be attributed to a reduced electron–triiodide reaction rate (k_M), shown by the measurement of I_M in the dark under 550 mV reverse bias, probably as a result of a restricted access of the triiodide ions to the semiconductor caused by the presence of the bulky triarylamine groups. Heterotriad H3|TiO_2 , whose photopotential was 31 mV lower than H5|TiO_2 , affords in the regenerative cell a 59 mV higher photovoltage, very probably because, in addition to a lower I_M , the reduction of $\text{H3}^+|\text{TiO}_2$ by iodide competes with the lateral electron transfer. Despite of the limitations caused by lateral charge percolation, the development of heterotriads as efficient charge-separation systems appears promising.

1.4.6 Photovoltaic Performances of Dye-sensitized Nanocrystalline Solar Cells

A scheme for the photovoltaic device used in the generation of electric power from light is shown in Figure 5. The mesoporous semiconductor oxide film is sandwiched between two conducting glass plates, its pore space being filled with a redox electrolyte or a hole conductor. We have shown above how the molecular properties of the sensitizer are chemically engineered to ascertain efficient electron injection from the dye excited state (S^*) into the conduction band of titanium dioxide. We also discussed how the recapture of the electrons by the oxidized dye (S^+) is intercepted by transferring the positive charge to a redox mediator M^+/M , i.e., the triiodide/iodide couple, present in the electrolyte and hence to the counterelectrode. Via this last charge transfer, in which the mediator is returned to its reduced state, the circuit is closed. The system converts light into electricity in a catalytic fashion, i.e., without permanent chemical transformation. The maximum voltage ΔV that such a device could deliver corresponds to the difference between the Fermi potentials in the two conducting electrodes, and thus to the difference between the redox potential of the M^+/M mediator couple and the conduction band edge potential of the semiconductor. Figure 21 compares the spectral dependence of the conversion efficiency of incident monochromatic light in electric current (*IPCE*) for *cis*- $[\text{Ru}^\text{II}(\text{dcbpy})_2(\text{NCS})_2]$ (\equiv “N3”) and $\text{Ru}^\text{II}(\text{tctpy})(\text{NCS})_3$ (\equiv “black dye”) sensitizers. Very high efficiencies of current generation approaching 0.8 were obtained. When corrected for the inevitable reflection and absorption losses in the conducting glass serving to support the nanocrystalline film, the yields are practically quantitative in the plateau region of the curves. However, the response of the “black dye” extends 100 nm further into the near-infrared than that of “N3”. The photocurrent onset is close to 920 nm, i.e., near the optimal threshold for single-junction converters. The overall conversion efficiency η of the photovoltaic cell can easily be calculated from

Figure 21. Typical spectral response curve of the incident photon-to-current conversion efficiency (IPCE) for a mesoporous TiO_2 electrode sensitized by “N3” and the “black dye”. A normalized solar irradiance spectrum under AM 1.5 conditions is superimposed for direct comparison.

the integral photocurrent density measured at short-circuit i_{sc} , the open-circuit photovoltage V_{oc} , the fill-factor of the cell f , and the intensity of the incident light I_{R} :

$$\eta = i_{\text{sc}} \times V_{\text{oc}} \times f / I_{\text{R}} \quad (61)$$

Figure 22 gives an example of the current–voltage characteristics of a nanocrystalline injection solar cell based on the *cis*- $[\text{Ru}^{\text{II}}(\text{dcbpy})_2(\text{NCS})_2]$ dye. The overall solar-to-electric conversion efficiency under standard AM 1.5 sunlight conditions, i.e., 1000 W m^{-2} incident intensity, is $\eta = 0.10$, which is commensurate with the performance of silicon-based conventional photovoltaic devices. Nanocrystalline injection solar cells based on the $\text{Ru}^{\text{II}}(\text{tctpy})(\text{NCS})_3$ sensitizer displayed similar results with a confirmed overall energy conversion efficiency as high as 10.4 %. Comparison of the latter value with the maximum thermodynamic conversion efficiency $\eta_0 = 0.27$, earlier discussed in Section 1.2.4, shows that theoretically avoidable losses amount to ca. 63 % of the available free energy. As inferred from the very high current yields obtained in such molecular photovoltaic devices, losses are essentially due to the waste of potential in electron transfer processes and to the dark current of the cell. The driving force of the charge injection process is minimal in the case of N3-sensitized TiO_2 in dry nitrile solvents. While partial degradation of the injected electron energy through trapping in the solid network cannot be neglected, it is apparent that the potential mismatch between the redox couples of the sensitizer S^+/S and the complex mediator I_3^-/I^- is responsible for a major part of the losses.

Figure 22. Photocurrent–voltage characteristic of a nanocrystalline photoelectrochemical cell sensitized with *cis*-[Ru^{II}(dcbpy)₂(NCS)₂]: $i(\text{sc})$ is the maximum (short-circuit) current density, and $V(\text{oc})$ the maximum (open-circuit) voltage delivered by the cell. The conversion efficiency is calculated by use of Eq. (61).

1.5 Water Cleavage by Visible Light

As pointed out by Allen Bard and Marye Anne Fox in a recent review [115], the photo-driven conversion of liquid water to gaseous hydrogen and oxygen (Eq. (62)),

is the “Holy Grail” of all photocatalytic reactions. It has been a long standing challenge of practical artificial photosynthetic systems. The hydrogen produced from sunlight and water can be subsequently employed in the catalytic reduction of carbon dioxide to produce fuels such as methane or methanol. The latter could also be used as feedstock for the production of organic chemicals. Alternatively, hydrogen could serve directly as a fuel for transportation purposes or for the production of electricity in fuel cells, without producing pollutants and greenhouse gases upon combustion. For a practical system, a conversion efficiency of at least 10 % is required, implying that the hydrogen and oxygen produced have a fuel value of at least 10 % of the solar energy incident on the system. As the peak solar power incident on Earth is about 1 kW m^{-2} a panel of 1 m^2 collector surface should produce hydrogen at a rate of about 36 L h^{-1} (at standard temperature and pressure) when exposed to direct sunlight.

As water is transparent to sunlight, a molecular sensitizer or semiconductor is required in order to absorb the solar photons and transform their radiant energy to generate the chemical potential required to split the H_2O molecules. The optimal absorption threshold for a single photoconverter has been calculated to be at an energy of 1.6 eV [116], implying that all solar photons below 770 nm should be absorbed. Such a system could split water with an efficiency of up to 30 %. Higher efficiencies of up to 42 % can be obtained by using a tandem device where two photosystems operate in series.

The “brute force” approach to achieve this goal is to employ a solid-state photovoltaic cell to generate electricity that is subsequently passed into a commercial-type water electrolyzer. Although efficiencies obtained are relatively high, i.e., close to 8 %, these devices are very expensive. Hence the price of hydrogen produced this way cannot compete with conventional sources. The long-term outlook is better for systems that borrow their principles from natural photosynthesis (see Section 1.4.1 above).

1.5.1 Analogs of Photosystem II of Green Plants

Researchers have long attempted to prepare catalysts capable of oxidizing water to oxygen (Eq. (17)), as the reaction constitutes the most difficult part in a complete water cleavage system. However, despite considerable efforts there are few man-made catalysts of any kind available, and none has made an impact on industrial chemistry [117, 118]. The difficulty of promoting this seemingly simple reaction has both thermodynamic and mechanistic origins. The catalyst must break the strong OH bonds on two water molecules (enthalpy 500 kJ mol^{-1}) in a concerted fashion. This has to be coupled to the removal of four protons and four electrons. The chemical intermediates formed during the process are so reactive that self-destruction of the catalyst often occurs. Nature solved this problem through evolution of a unique metalloenzyme required for oxygenic photosynthesis in all plants and cyanobacteria. This enzyme is called the Photosystem II water-oxidizing complex, or WOC. Its active site comprises an oxo-bridged tetramanganese cluster, one Ca^{2+} ion, and one or more Cl^- ions. In association with tyrosyl this core catalyzes reaction (17) using a chlorophyll cation radical as terminal electron acceptor.

The most intensively studied molecular systems mimicking the action of the WOC are based on the μ -oxo-bridged ruthenium dimer [*cis*-(bpy) $_2\text{Ru}(\text{OH}_2)]_2\text{O}^{4+}$, where each ruthenium is associated with two bipyridyl ligands and one water molecule. The catalytic water oxidation cycle involves abstraction of two electrons from each of the Ru(II) centers forming two dioxoruthenium(IV) moieties which convert back to the starting state under oxygen release and subsequent re-aquation of the ruthenium metal centers [119].

1.5.2 Colloidal Semiconductor Systems

Photocatalytic water-cleavage systems based on aqueous dispersions of semiconductor particles were extensively studied in the 1980s and this work has been

reviewed [120]. They have the advantage of being cheap but their efficiency is generally below 1 %. The additional drawback is that hydrogen and oxygen are generated simultaneously. Apart from the problem of gas separation, this produces a slowdown of the photoreaction as the two gases accumulate and back-react with each other. A way to avoid the latter problem is to separate the hydrogen and oxygen, generating half-reactions as reported recently by Arakawa and co-workers [121]. However, the efficiency of the process remains low.

1.5.3 Tandem Systems for Water Cleavage by Visible Light

The most promising approach to reach the goal of water cleavage by visible light is by way of a tandem system. The main reason for this is that the constraints imposed by thermodynamics are relaxed when eight photons of light are used instead of four to accomplish the production of two molecules of hydrogen and one molecule of oxygen from water. A tandem system is particularly favorable when complementary parts of the solar spectrum are exploited by the two photosystems operating in series. The maximum thermodynamic efficiency of such device is 42 %.

Khaselev and Turner [122] reported on a direct water-electrolysis system based on a novel, integrated, monolithic photoelectrochemical cell. This was patterned after the GaInP₂/GaAs p/n, p/n tandem cell device grown at the National Renewable Energy Laboratory in Golden, Colorado. The solid-state tandem cell consists of a GaAs bottom cell connected to a GaInP₂ top cell through a tunnel diode interconnect. The top p/n GaInP₂ junction, with a bandgap of 1.83 eV, is designed to absorb the visible portion of the solar spectrum; and the bottom p/n GaAs junction, with a bandgap of 1.42 eV, absorbs the near-infrared portion of the spectrum transmitted through the top junction. The conversion efficiency achieved was 12 %.

A tandem device that achieves the direct cleavage of water into hydrogen and oxygen by visible light was developed in collaboration with two partner groups from the Universities of Geneva and Bern [123]. This is based on the in-series connection of two photosystems. A thin transparent film of nanocrystalline tungsten trioxide or ferric oxide absorbs the blue part of the solar spectrum (Eq. (63)).

The valence band holes (h^+) created by bandgap excitation of the WO₃ or Fe₂O₃ serve to oxidize water to oxygen:

while the conduction-band electrons are fed into the second photosystem. The latter consists of the dye-sensitized nanocrystalline TiO₂ film. It is placed directly behind the WO₃ film, capturing the green and red part of the solar spectrum that is transmitted through the top electrode. The photovoltage generated by the second photosystem enables the generation of hydrogen by the conduction-band electrons:

Figure 23. The Z-scheme of biphotonic water photolysis.

The overall reaction corresponds to the splitting of water by visible light.

There is close analogy to the Z-scheme operative in the light reaction of photosynthesis in green plants (Figure 3). This is illustrated by the electron flow diagram shown in Figure 23. In green plants, there are also two photosystems connected in series, one affording water oxidation to oxygen and the other generating the NADPH used in carbon dioxide fixation. As discussed above, the advantage of the tandem approach is that higher efficiencies than with single junction cells can be reached if the two photosystems absorb complementary parts of the solar spectrum. At present, the overall AM 1.5 solar light to chemical conversion efficiency achieved with this device stands at 4.5 %. Figure 24 shows such a cell producing hydrogen and oxygen bubbles vigorously under visible-light illumination. Present endeavors aim at further improving the efficiency of the device.

1.6 Future Outlook and Concluding Remarks

Intensive research is being carried out around the world, focusing on the following issues:

- 1) the molecular design and synthesis of new sensitizers having an enhanced near-infrared light response, examples being phthalocyanines or the black dye discussed above;

Figure 24. Decomposition of water by visible light in a tandem cell consisting of a mesoporous WO_3 film and a mesoporous dye-sensitized TiO_2 film which is superimposed.

- 2) achievement of a better understanding of the interface, including experimental and theoretical investigation of dye adsorption processes;
- 3) the analysis of the dynamics of interfacial electron transfer processes down to the femtosecond time domain;
- 4) the unraveling of the factors that control electron transport in nanocrystalline oxide semiconductor films; and
- 5) the replacement of the liquid electrolyte by solid materials that serve as a hole conductor.

A great advantage of dye-sensitized cells is that they can be used to produce directly high-energy chemicals from sunlight. Such “photosynthetic” devices solve the principle problem of conventional photovoltaic cells, i.e., the lack of capacity for energy storage. The “Holy Grail” of all photoconversion processes is the splitting of water into hydrogen and oxygen by sunlight, and the improvement of the tandem devices described above will be one of the primary targets of future research. Rapid prog-

ress is expected in these areas as an impressive number of competent teams around the world are actively pursuing this research. These systems will undoubtedly promote the acceptance of renewable energy technologies, not least by setting new standards of convenience and economy.

Acknowledgments

Recognition is due to the members of the Laboratory of Photonics Interfaces of the Swiss Federal Institute of Technology (EPFL), some of whose work is referenced below; to those industrial organizations whose interest in the molecular photovoltaic system has induced them to license the concept and thereby support our research; to EPFL and FNRS (Swiss National Science Foundation) for financial support; and to OFEN (Swiss Federal Office of Energy) for past encouragement and support. Thanks are also due to Dr. Pierre Bonhôte for valuable help in the writing of Section 1.4.5.

2 Batteries

Catia Arbizzani, Marina Mastragostino, and Francesca Soavi

2.1 Introduction

Volta's discovery of the pile 200 years ago (1799) ushered in the age of electrochemistry. Today, while the battery remains the most widespread practical application of electrochemistry, it is perhaps just as true that the battery is also the most widespread application of electron transfer, the phenomenon at the basis of its operation.

Unlike the past, the term "battery" is now commonly used to indicate either one or more electrochemical cells in series or in parallel. The terms "primary" and "secondary" cell were introduced to distinguish the device's characteristics, i.e., the ability to work until the reactants are exhausted or to sustain both the forward and the reverse processes, reactants \rightarrow products and products \rightarrow reactants. Today secondary cells are also called rechargeable batteries.

Batteries accomplish two functions:

- 1) to convert chemical into electric energy, i.e., to act as a source of electric energy, which is true for both nonrechargeable and rechargeable systems;
- 2) to store the electric energy supplied by an external source, i.e., to act also as energy storage systems, which is true only for rechargeable batteries.

The latter batteries are used for such different applications as in consumer electronics, in vehicles for starting, lighting, and ignition (SLI) and for traction, as emergency power supplies, in load-leveling systems of electric power stations to supply peak demand, and as systems to couple with alternative energy sources.

The battery's energy, which is the amount of electric energy that can be delivered (generally expressed in watt-hours, Wh) is directly related to its size: Table 1 gives a classification of the various battery types associated with their uses. The energy range extends over many orders of magnitude, from 0.1 mWh (single cell) for microelectronic applications to 100 MWh (several cells with in-series or parallel arrays) for load-leveling in electric power stations.

Table 1. Battery types according to size [1] (by permission of Arnold: C.A. Vincent and B. Scrosati, *Modern Batteries. An Introduction to Electrochemical Power Sources*, 2nd edition, 1997).

Type	Energy	Applications
Miniature batteries	0.1 mWh–2 Wh	electric watches, calculators, implanted medical devices
Batteries for portable equipment	2 Wh–100 Wh	cellular phones, laptop computers, flashlights, toys, portable radios, televisions
SLI batteries (starting, lighting and ignition)	100–600 Wh	cars, trucks, buses, tractors
Vehicle traction batteries	20–630 kWh	forklift trucks, locomotives
Stationary batteries	250 Wh–5 MWh	emergency power supplies, local energy storage, remote relay stations
Load-leveling batteries	5–100 MWh	spinning reserve, peak shaving, load leveling

From an historical point of view, it is the introduction of telegraph systems, in the late 1830s, that demonstrated the signal importance of Volta's discovery. Following Volta, Planté developed in 1859 the first lead–acid rechargeable battery and Leclanché in 1866 the primary zinc–manganese dioxide cell bearing his name. In 1890 the invention of the nickel–iron rechargeable cell by Edison opened the door to the development of the nickel–cadmium cell, first proposed in 1899 by Jungner. The advent of the rechargeable systems was greatly stimulated by the demand from the incipient motor car industry, the growing public interest in which was also being fed by the unforgettable exploit like that of the Belgian race driver Jenatzy who, in 1899, established the land speed record of 66 miles per hour in his streamlined electric *Jamais Contente*. However, the initial spurt of enthusiasm for electric vehicles petered out in the next two decades as they became less and less competitive with the petroleum-powered car.

The great discoveries ameliorating the standard of living by the end of the 19th century stimulated the demand—and of course the research—for new, improved batteries. This holds as much for the present as it did for the past. Indeed, a notable impulse to battery research and development was the invention of the transistor in 1950, broadening the range of battery applications from electronics to medical science and the conquest of outer space. With the launch in 1957 of the *Sputnik*, the Soviet satellite whose communications and operating systems were powered by silver–zinc primary cells, the space race was on. In 1960 the first successful pacemaker, containing ten zinc–mercuric oxide primary cells and two transistors, was implanted into a human being. The “oil crisis” in the 1970s was the driving force behind the search for renewable energy sources, while the last two decades of the 20th century saw great advances in circuit miniaturization, an exponential proliferation of portable products requiring primary cells, and a spectacular growth of cellular phones and laptop computers demanding greater performance than ever before from rechargeable systems.

All of this has shifted the focus of research in rechargeable batteries from nickel–cadmium to nickel–metal hydride and lithium-ion systems, with additional impetus from the heightened environmental consciousness in the 1990s extending the range of focus to the development of nonpolluting forms of transport. Although recent advances in automobile engines have made new cars less polluting than older ones, the increase in vehicle numbers offsets the benefits of cleaner engines. Several legislative measures and actions, such as the establishment in 1991 of the US Advanced Battery Consortium (USABC), have also helped to accelerate the development of advanced batteries, such as the lithium-based ones for use in electric vehicles.

Apart from its historical interest, this brief survey over the centuries from 1800 to 2000 helps underscore the fact that key developments in battery research and technology have always come in response to specific sector demands that have in turn followed signal scientific advances. Nowadays, the three main rechargeable systems are the lead-, nickel-, and lithium-based batteries. While the first two, with their roots in the last century, are undergoing continual refinement to improve their performance in today's applications, the last is the result of the most recent research into new materials and the one that offers greater expectations.

The basic thermodynamic and electrochemical kinetic concepts involved in batteries and the parameters used to evaluate their performance are summarized in Section 2.2. The most widespread primary and rechargeable systems are described by highlighting the most recent advances in Section 2.3. Supercapacitors and fuel cells, whose importance in the field of energy conversion is growing, are also briefly treated in this section. The lithium-based rechargeable systems, the most advanced batteries with the highest performance, are discussed in detail in Section 2.4, with particular emphasis on the new materials on which these batteries are based.

2.2 Basic Aspects

A spontaneous electron transfer process from one ionic species A^{x+} to another B^{y+} , wherein A^{x+} donates electrons that are accepted by B^{y+} , as in the redox reaction (1),

can take place by chemical reaction in homogeneous solution or by heterogeneous electrochemical reaction in an electrochemical cell. The condition for the occurrence of such a spontaneous electron transfer process is a decrease in the reaction's free energy. The electrochemical cell for such redox reactions as (1) is based on two chemically inert metal electrodes—which act as electron sink and source—immersed in solutions containing the A^{x+} and $A^{(x+1)+}$ and the B^{y+} and $B^{(y-1)+}$ ions, respectively; a separator between the two solutions prevents their mixing but permits their electric contact. The A^{x+} ions donate electrons to one metal electrode

by changing their oxidation state, as in

and the B^{y+} ions accept electrons from the other electrode by changing their oxidation state, as in

via the connection by external resistance load of the two metal conductors. This enables the charge to flow round the circuit, which is closed by the ion movement in the solution; hence, the reaction (1) can progress spontaneously and continuously as the sum of the two half-reactions (2) and (3), which involve charge transfer at the metal–solution interfaces. The amount of the $A^{(x+1)+}$ and $B^{(y-1)+}$ ions produced is related by Faraday's laws to the total charge transferred across the metal–solution interfaces. The most important feature is that in an electrochemical cell the spontaneous progress of the reaction (1), driven by its free energy decrease, includes the spontaneous electron flow through the external resistance load and, hence, a direct conversion of the reaction's chemical energy into electric energy takes place; this is basically how a battery works under the discharge process. Batteries, by converting the chemical energy of their electroactive materials directly into electric energy, are portable sources of electric energy and, hence, a widespread application of the electron transfer process.

More generally, a battery consists of two electrodes separated by at least one electrolyte phase. A convenient notational representation of a battery is to write the chemical composition of the phases composing it in the order in which the phases are connected, and to indicate each phase boundary by a vertical line. A double vertical line indicates the contact zone of two electrolyte phases.

During battery discharge, as shown in Figure 1 with the Daniell cell as an example, the electrode (a zinc rod immersed in a zinc sulfate solution) at which the oxidation reaction takes place is called the anode, and is the negative electrode. The other electrode (a copper rod immersed in a copper sulfate solution) at which the reduction reaction takes place is called the cathode and is the positive electrode. The electron flow in the external circuit is from anode to cathode (the current, i , conventionally flows in the opposite direction to that of the electrons), and in the electrolyte phase the ionic flow closes the circuit. The net result of the charge flow round the circuit is the cell reaction, which is made up of the two half-reactions of charge transfer that describe the chemical changes at the two electrodes.

There are also batteries in which the sum of the two electrode half-reactions produces not a chemical reaction but the transfer of a species from one electrode to the other. Such cells are called concentration cells to distinguish them from those in which a chemical reaction takes place.

A battery in which the cell reaction is reversed when the current is made to flow through the cell in the opposite direction by an external electric energy source is a rechargeable battery. During battery recharge the electric energy is converted into chemical energy; hence a rechargeable battery is a storage and energy conversion

Figure 1. Daniell cell under discharge.

device. In a battery under charge the electrode at which the reduction reaction takes place, i.e., the cathode, is the negative electrode, and that at which the oxidation reaction takes place, i.e., the anode, is the positive electrode. It is worthwhile pointing out that in a battery under discharge the negative electrode is the anode whereas under charge it is the cathode.

When the current does not flow through battery the measurable difference in electric potential between the terminals of the two electrodes is the result of all the equilibrium potential differences at the interphase between the conducting phases in contact. In the example of the Daniell cell, with both electrodes having copper terminals, there are three interfacial potential differences (apart from the small liquid junction potential difference at the contact between the two electrolyte phases): one potential difference at the contact between the zinc rod and the copper terminal (Zn/Cu) and two potential differences at the metal–solution interphases (Zn/Zn²⁺ and Cu/Cu²⁺), which are mainly due to the charge transfer processes.

Let us now look in greater detail at how the potential difference at the metal–solution interphase is built up. When a metal M, such as zinc or copper, enters into contact with a solution containing one of its salts, e.g., zinc sulfate or copper sulfate, at the interface there will be an exchange of M^{x+} metal ions between the two phases. At the beginning, under conditions such that there are more M^{x+} ions leaving the metal crystal lattice than M^{x+} ions entering it, the metal and the solution phases become progressively charged: an excess of electrons builds up on the metal side and an excess of M^{x+} ions builds up on the solution side so that an electrical potential difference develops at the interphase. This potential difference in turn affects the charge transfer rates by depressing the rate at which the M^{x+} ions

leave the metal, i.e., the rate of the oxidation reaction, and by increasing that at which the M^{x+} ions enter the metal, i.e., the rate of the reduction reaction, until the rates of the two processes become equal. At this point a dynamic equilibrium is established—a very small quantity of charge has been transferred—and the difference in the electric potential at the interphase is the “interphase equilibrium potential difference”. A similar description can be given for the buildup of the equilibrium potential difference at the metal–solution interphase of a chemically inert metal M in a solution with the oxidized $A^{(x+1)+}$ and reduced A^{x+} ions. The inert metal acts as the source and sink of electrons: some electrons from the conduction band of the metal are accepted by the $A^{(x+1)+}$ oxidized species in solution and some electrons are donated to the metal by the A^{x+} reduced species in solution. At the beginning the reduction and oxidation rates are unequal, and the metal and solution become progressively charged until the equilibrium is established, resulting in the attainment of the interphase equilibrium potential difference.

When the current flows through the battery—a net reduction reaction takes place at one electrode and a net oxidation reaction takes place at the other—the potential difference at each metal–solution interphase is different from that at equilibrium.

Since it is impossible to measure the individual electric potential differences at the phase boundaries, we shall hereinafter speak only in terms of the difference in electric potential across the two terminals connected to the electrodes of the battery. When in a battery the current is not flowing or tends to zero, the measurable potential difference across the two terminals is called the open-circuit voltage (OCV), V_{oc} , and it represents the battery’s equilibrium potential (or voltage). Since it is related to the free energy of the cell reaction, the OCV is a measure of the tendency of the cell reaction to take place. Indeed, while the conversion of chemical into electric energy is regulated by thermodynamics, the behavior of a battery under current flow (the current is a measure of the electrochemical reaction rate) comes under electrochemical kinetics.

2.2.1 Thermodynamics and Electrochemical Kinetics

At constant temperature (T), pressure (P) and composition, the free energy of cell reaction ΔG , where $\Delta G = \sum v_i \mu_i$ (v_i stoichiometric coefficients and μ_i chemical potentials), is a measure of the maximum electric work (W_{el}) the battery can deliver in association with n moles of transferred electrons; the relevant thermodynamic equation is

$$-\Delta G \geq W_{el} \quad (4)$$

The “equals” sign is valid for a reversible ($i \rightarrow 0$) conversion; the “greater than” sign is valid for an irreversible conversion (finite i). Hence, an electrochemical cell delivers electric work equal to the free energy change only at infinitesimal current flow: under these conditions the cell potential is the OCV and the electric work delivered is the maximum $W_{el,max} = nFV_{oc} = -\Delta G$ (n is the number of moles of transferred electrons and F the Faraday constant).

During the reversible conversion of chemical energy into electric work, heat exchange with the surroundings also takes place, and it is equal to $T\Delta S$, ΔS being the cell reaction entropy change. At constant T , the enthalpy change is $\Delta H = \Delta G + T\Delta S$, and hence a positive ΔS value implies that the electrochemical cell delivers electric work greater than the amount of heat that the reaction produces when it takes place chemically at constant P , i.e., greater than ΔH .

The flow of a finite amount of electric current always determines a certain degree of irreversibility: part of the chemical energy thermodynamically available as electric energy is dissipated as heat because of various “resistances” in the electrolyte and in the electrodes to the transfer of charge through the cell. The potential difference across the two electrode terminals under the flow of a finite current, V_i , is always less than V_{oc} during spontaneous discharge, and it is lower the higher the current flowing, so that only a part of the chemical energy is used to supply electric work. The other part, dissipated as heat, is $Q = T\Delta S - nF(V_{oc} - V_i)$. In the limiting case of short-circuit current, there being no electric work produced, all the chemical energy is dissipated as heat, and the heat emitted to the surroundings is equal to ΔH .

The measurements of OCV, which are taken by high-resistance ($>10^7 \Omega$) electronic voltmeters to satisfy the requirements of $i \rightarrow 0$, make it possible to determine the free energy, the entropy and the enthalpy of cell reactions, in addition to activity coefficients, equilibrium constants, and solubility products.

Given that the cell reaction is composed of the two half-reactions at the electrodes, the battery's V_{oc} can also be estimated as the difference in the equilibrium potentials of the positive and negative electrode (Eq. (5)).

$$V_{oc} = V_{eq+} - V_{eq-} \quad (5)$$

The electrode equilibrium potential, $V_{eq,e}$, as related to the half-reaction $Ox + ne^- \rightarrow Red$, is given by the the Nernst equation:

$$V_{eq,e} = V_{eq}^\circ - (RT/nF) \ln a_{Red}/a_{Ox} \quad (6)$$

where V_{eq}° is the standard potential, and a_{Red} and a_{Ox} are the activities of the reduced and oxidized species. The equilibrium potential of each electrode is not a potential difference at the metal–solution interphase, but it is a physically measurable quantity in that it is defined as the potential difference between the terminals of a cell based on the electrode (half-cell) in question and the standard hydrogen electrode (SHE); to the SHE is arbitrarily assigned a potential of zero volts.

At the electrode equilibrium potential $V_{eq,e}$ the cathodic current, i_c , and the anodic one, i_a , which represent the reduction and oxidation reaction rates at the electrode–solution interphase, respectively, are equal and the net current $i = |i_c| - i_a$ is zero; the $|i_c| = i_a$ value is called the exchange current, i_0 . The passage of net current ($i \neq 0$) through the cell causes some changes with respect to equilibrium, and these are generically indicated by the term “polarizations”. The difference between the value of the electrode potential under flowing current, $V_{i,e}$, and that of the equilib-

rium potential, $V_{\text{eq,e}}$, is called the electrode overvoltage, η_e :

$$\eta_e = V_{i,e} - V_{\text{eq,e}} \quad (7)$$

During the discharge and charge processes of a battery, various forms of charge transfer are involved:

- 1) electron flows in electronic conductors (electrode materials, terminals, load resistance);
- 2) ion flows in the electrolyte;
- 3) charge transfer (ions and electrons) at the electrode–electrolyte interphases.

The charge flow through each part of the circuit is the same, so as to maintain the electroneutrality condition in each part, and the charge transfer process which takes place at the lowest rate becomes the current-limiting step.

As noted above, the passage of a finite current through an electrochemical cell causes a certain shift from the equilibrium potentials. During discharge the battery's potential is less than its equilibrium value V_{oc} , i.e., the cathode's potential is less positive and the anode's is less negative with respect to their equilibrium potentials. By contrast, during the charge process the applied potential has to be higher than V_{oc} , i.e., the cathode's potential has to be more negative and the anode's more positive with respect to their equilibrium potentials. Thus it is important to know how far the cell potential is from V_{oc} , i.e., it is important to determine the cell overvoltage, $\eta = V_i - V_{\text{oc}}$, which is responsible for the energy dissipation, in order to estimate the battery performance.

The main causes of overvoltage are:

- 1) the ohmic drop (iR , ohmic overvoltage) in the electrolyte, separators, electrodes, and terminals;
- 2) the electrode losses (η_e , electrode overvoltages), which include the activation overvoltage (η_{act}) related to the charge transfer rate at the electrode–electrolyte interphase and the concentration overvoltage (η_{conc}) related to the depletion or accumulation of electroactive materials generally near the electrode surface.

Therefore, during the charge process of an electrochemical cell, a potential V_i , which is the sum of the cell equilibrium potential V_{oc} , the cathodic overvoltage ($\eta_{e,c}$), the anodic overvoltage ($\eta_{e,a}$) and the ohmic drop (Eq. (8)),

$$V_i = V_{\text{oc}} + |\eta_{e,c}| + \eta_{e,a} + iR \quad (8)$$

must be applied by an external source; whereas during a discharge process the overvoltages and the ohmic drop have to be subtracted from V_{oc} in order to obtain the potential V_i supplied to the external system (Eq. (9)).

$$V_i = V_{\text{oc}} - |\eta_{e,c}| - \eta_{e,a} - iR \quad (9)$$

A representation of the two situations is shown in Figures 2a and 2b; some details on the ohmic, activation and concentration overvoltages are reported below.

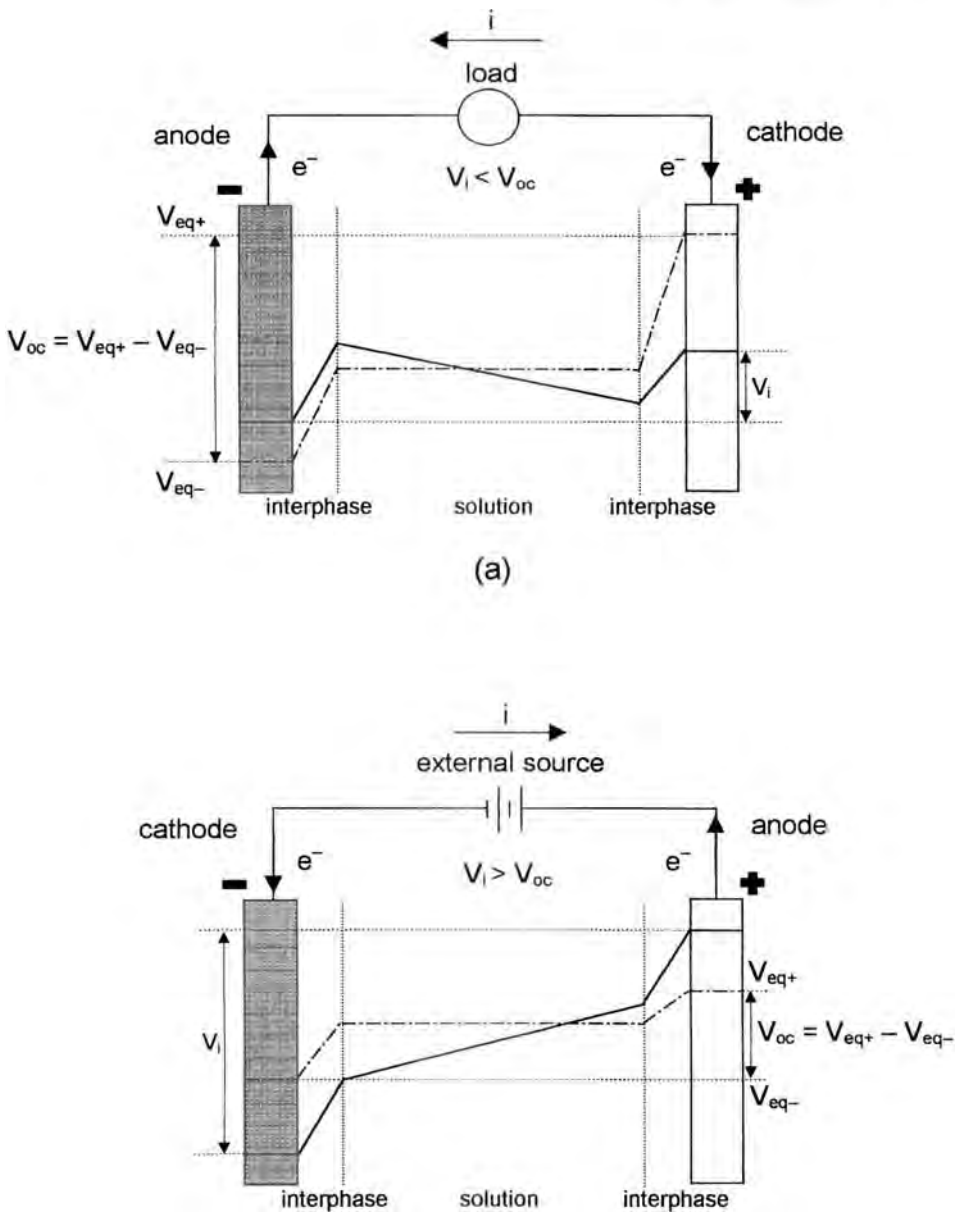

Figure 2. Battery a) under discharge and b) under charge.

The ohmic potential drop, iR , is due to the sum of the internal resistances of the bulk phases within the cell, $R = \sum x_i / (A_i \sigma_i)$, where for each i -phase x is the thickness, A the geometric area and σ the conductivity. While it is generally simple to evaluate the ohmic potential drop due to the electrolyte bulk, in some cases it is difficult to distinguish between the ohmic and electrode polarization taking place in the electrode bulk, especially when porous or composite electrodes are involved. As the main polarization losses in batteries at moderately high current densities are due to the ohmic potential drop, efforts in battery design have to focus on increasing the conductivity of the electrolyte phase, reducing the resistance of electrode materials, choosing suitable current collectors, and minimizing the distance between the electrodes while maintaining a uniform current distribution.

In the case of sufficiently high mass transport, i.e., the absence of concentration polarization phenomena, and when the electrochemical process is controlled by the charge transfer rate at one electrode, the dependency of the current on the electrode potential, $V_{i,e}$, is given by the Butler-Volmer equation (Eq. (10)),

$$i = nFAk_0 \{ C_{Ox,e} \exp[-\alpha nF(V_{i,e} - V_{eq}^\circ)/RT] - C_{Red,e} \exp[(1 - \alpha)nF(V_{i,e} - V_{eq}^\circ)/RT] \} \quad (10)$$

where $C_{Ox,e}$ and $C_{Red,e}$ are the concentrations of the species Ox and Red on the electrode surface, which are equal to those in the solution bulk C_{Ox} and C_{Red} , k_0 is the exchange constant, i.e., the charge transfer rate constant at the standard equilibrium potential V_{eq}° , α the transmission coefficient, and A the electrode area.

Equation (10) expressed in terms of overvoltage ($\eta_e = V_{i,e} - V_{eq,e}$) becomes

$$i = i_0 \{ \exp(-\alpha nF\eta_e/RT) - \exp[(1 - \alpha)nF\eta_e/RT] \} \quad (11)$$

where $i_0 = nFAk_0 C_{Ox}^{(1-\alpha)} C_{Red}^\alpha$, which demonstrates the i - η_e curve's dependence on the α and k_0 parameters.

At high overvoltage, $|\eta_e| > 100$ mV, only the cathodic or anodic current contributes significantly to the net current; e.g., for cathodic overvoltages, Eq. (11) becomes

$$i = i_0 \{ \exp(-\alpha nF\eta_e/RT) \} \quad (12)$$

and the activation overvoltage can be calculated from Eq. (13):

$$\eta_{act} = (RT/\alpha nF) \ln i_0 - (RT/\alpha F) \ln i \quad (13)$$

When the mass transport rate (to simplify, here due only to diffusion) is not high enough, particularly at high current values, a concentration gradient of the electroactive species arises in the region near the electrode: in the case of cathodic current, the concentration of the oxidized species diminishes at the electrode surface, whereas that of the reduced species increases. The current, under linear diffusion control and at constant concentration gradient, is given by

$$i = nFAD_{Ox}(C_{Ox} - C_{Ox,e})/\delta \quad (14)$$

where D_{Ox} is the diffusion coefficient and δ is the diffusion layer thickness. The diffusion current reaches the maximum value (limit current, i_{lim}) when the concentration at the electrode surface is zero ($C_{\text{Ox},e} = 0$):

$$i_{\text{lim}} = nFAD_{\text{Ox}}C_{\text{Ox}}/\delta \quad (15)$$

The concentration changes at the electrode surface due to mass transport limitations are responsible for the concentration overvoltages. When a reduction process takes place (e.g. $\text{Zn}^{2+} + 2\text{e}^- \rightarrow \text{Zn}$), a concentration of the oxidized species at the electrode surface ($C_{\text{Ox},e}$) lower than that in the bulk makes the current, at a given potential, lower than that in the absence of an ion diffusion limitation, and to achieve the same current value an overvoltage (concentration overvoltage) must be imposed. This concentration (or diffusion) overvoltage can be calculated from Eq. (16):

$$\eta_{\text{conc}} = (RT/nF) \ln(C_{\text{Ox},e}/C_{\text{Ox}}) \quad (16)$$

By expressing $C_{\text{Ox},e}/C_{\text{Ox}}$ in terms of diffusion current, the η_{conc} can be estimated from Eq. (17).

$$\eta_{\text{conc}} = (RT/nF) \ln(1 - i/i_{\text{lim}}) \quad (17)$$

Having thus examined how the various polarizations affect the behavior of an electrochemical cell, we can state that a low solution resistance, electrode processes characterized by a high exchange constant, and a high concentration of electroactive species are fundamental requisites for batteries with high efficiency in converting chemical into electric energy.

Let us to conclude this section by stressing that direct conversion of chemical into electric energy by electrochemical systems is a significantly more efficient method of energy conversion than the indirect one based on chemical reactions, in which chemical energy is released as heat that in turn is converted into work (W) by a thermal engine. Limitations intrinsic (Carnot limitations) to the indirect method enable “an ideal engine” to reach a maximum conversion efficiency value, $\varepsilon = -W/\Delta H$, in the 30–50 % range; values drop to 20–30 % in real systems in practice.

The direct electrochemical method makes it possible to produce maximum electric work equal to $-\Delta G$. The values for ΔG at room temperature are usually close to those for ΔH ($T\Delta S$ is small compared with ΔH and it may be positive or negative) and the maximum efficiency value for direct conversion, $\varepsilon_{\text{max}} = -nFV_{\text{oc}}/\Delta H$, may be slightly lower or higher than 100 % depending on the sign of ΔS . The practical conversion efficiency is lower: a part of the energy, as reported above, is spent in propagating the reaction, and the drop is related to the current flow. The practical conversion efficiency of the electrochemical system can be estimated from Eq. (18), and the fuel cells operate in regimes with practical conversion efficiency values in the 60–70 % range, significantly higher than that of the indirect energy conversion methods.

$$\varepsilon = -(nFV_i/\Delta H) = -(nF/\Delta H)(V_{\text{oc}} - \eta_{\text{e,a}} - |\eta_{\text{e,c}}| - iR) \quad (18)$$

2.2.2 Battery Performance

Battery performance is rated on the basis of the charge capacity, available energy, delivered power, and charge retention during OCV conditions; for rechargeable systems, the coulombic efficiency and stability to repeated charge–discharge cycles are also important parameters.

The *theoretical capacity* [Ah] is the charge that a battery delivers when the utilization of its electroactive materials is 100 %, i.e., when the cell is completely discharged (100 % depth of discharge, DOD); when the battery is partially discharged (DOD < 100 %), the corresponding delivered charge is the *practical capacity*. To compare the performance of batteries, the key parameter is the *specific capacity* which includes both gravimetric [Ah kg⁻¹] and volumetric [Ah L⁻¹] capacity. These are obtained by dividing the battery capacity by the mass and the volume, respectively, of its electroactive materials.

The *theoretical energy* E_T [J or Wh] is the available energy for n moles of transferred electrons and is given by the related change in free energy $E_T = -\Delta G = nFV_{oc}$. The *practical energy* depends on the discharge conditions and is given by Eq. (19):

$$E_p = \int_0^{nF} V_i dq = \int_0^t V_i i dt \quad (19)$$

where the cell voltage V_i is farther from the OCV, the higher the discharge current. To compare different systems, important parameters are the *specific energy* [Wh kg⁻¹] and *energy density* [Wh L⁻¹], which can be obtained by dividing theoretical energy by the mass and volume of the electroactive materials, respectively.

The *power* delivered by a battery is given by the product of the current flow and the related cell voltage, $P = iV_i$. The *maximum power* of a battery can be estimated by measuring V_i as a function of current; *specific power* [W kg⁻¹] and *power density* [W L⁻¹] are the parameters used to compare the performance of batteries.

Electroactive materials of a battery, in order to reach the goals of high specific energy and energy density, must meet two important requirements:

- 1) high specific capacity (gravimetric and volumetric, i.e., a high number of available charge carriers per mass and volume unit) and
- 2) a high standard potential of the redox reaction for the positive electrode and a low standard potential of the redox reaction for the negative electrode.

A rechargeable battery also requires highly reversible half-reactions at the two electrodes to maintain its capacity performance for hundreds of charge–discharge cycles. *Coulombic efficiency* values (η) of the charge–discharge cycles (Eq. (20))

$$\eta = \int_0^t i_{\text{disch}} dt / \int_0^t i_{\text{ch}} dt \quad (20)$$

close to 1 are required for a long cycle life; this is true only if the electroactive materials of both electrodes have a near-unity coulombic efficiency of their charge–

discharge processes. The *cycle life* indicates the number of charge–discharge cycles a battery can withstand before its performance drops to a fixed limit, and depends on the DOD. Another important feature of rechargeable batteries (vital for primary batteries) is a low self-discharge for a long shelf life. The *self-discharge* is expressed as the percentage of charge no longer available, with respect to the theoretical capacity, after a storage period in open-circuit voltage conditions.

Both the polarization and discharge curves are used to represent the battery operating conditions. The former is the plot of cell voltage V_i vs. current and shows polarization phenomena; the latter is the plot of the cell voltage V_i at constant current or with an applied constant external load. The abscissa may be calibrated in terms of capacity, percentage of theoretical capacity, or time. A useful method to characterize and compare the discharge curves is to express the discharge currents in terms of theoretical capacity (C-rate). An *C-rate* of x indicates that the theoretical capacity of the cell [Ah] is delivered in a time $t = 1/x$ [h]. For example, 2C, C/2 and C/5 signify discharge times of 0.5, 2, and 5 h, respectively: for a 1-Ah cell, discharge at 2C, C/2 and C/5 means a discharge current of 2 A, 0.5 A, and 0.2 A, respectively.

For a detailed treatment of Section 2, see Refs. [1–4].

2.3 Energy Conversion Systems

The demand for both primary and secondary cells, the former being “non-reusable” products because they are unrechargeable, and the latter “renewable” because they are rechargeable, has been expanding in recent years. The total volume of the worldwide battery market in 1997 was about \$34 billion, with the primary-cell segment accounting for about 30 % and the lead–acid system for over half of the remaining rechargeable battery share [5]. For example, Japanese sales trends from 1985 to 1997 for secondary batteries are depicted in Figure 3 [6]. It is worth highlighting that since 1997 there has been a surge in Japanese turnover of rechargeable batteries due to the growing demand in the cellular phone market (by late April 1998 registered cellular phones in Japan exceeded 33 million), almost every one of these units being equipped with a lithium-ion system [6].

2.3.1 Primary Cells

Figure 4 shows a comparison of practical energy density and specific energy of primary batteries. Two groups can be distinguished: the zinc-based and lithium-based systems.

Zn-based systems

The term zinc–carbon usually indicates both the Leclanché cell, consisting of Zn, manganese dioxide, and an aqueous solution of NH_4Cl and ZnCl_2 , and the zinc

Figure 3. Secondary battery sales in Japan by type.

Figure 4. Practical energy density and specific energy of primary systems.

chloride cell, in which ZnCl_2 completely replaces the NH_4Cl . The Leclanché cell and the electrode reactions may be written as:

The reaction products at both electrodes give rise to further reactions so that it is not possible to represent only one cell reaction.

The zinc chloride system and cell reaction can be written as:

The advantage of the latter system with respect to the Leclanché battery is closely related to the electrolyte: insoluble reaction products are less involved and this results in an operating temperature that ranges further down the scale, and higher current densities.

Another variant of the Leclanché cell is the so-called alkaline manganese cell, which with its cell reaction may be written:

The advantages of this cell with respect to the Leclanché are higher practical capacity (up to ten times the Ah capacity of zinc–carbon cells at high discharge currents), longer shelf life and superior low-temperature performance. Figure 5 compares the performance of a D-size alkaline cell, under 2.25Ω continuous test, with the other zinc–manganese dioxide primary systems of the same size. Although the alkaline battery is more expensive than the Leclanché or the ZnCl_2 batteries, it has rapidly become the choice in the ever-widening field of consumer electronics, especially in the USA, where the production of the traditional zinc–carbon systems has been discontinued (Leclanché and ZnCl_2 are now imported there). The alkaline system is also of interest in that it is the basis of a secondary system (Section 2.2.3, under “Zn-based systems”).

Continuous demands from various sectors of the market for improved performance capabilities in the alkaline cells has spurred major research efforts in materials science, leading to a key redesign of their internal structure. For example, mercury, initially used to amalgamate zinc, has been replaced with other zinc-alloying agents; organic corrosion inhibitors have been added; critical impurities of the manganese dioxide cathode have been notably reduced; and the composition of the KOH gelling agents holding the zinc powder in the anode compartment has been modified. As a result, service life has increased by over 30 % compared with 10 years ago and the high current pulse capability has been upgraded [5].

Figure 5. Performance of D-size zinc-manganese dioxide primary systems under $2.25\ \Omega$ continuous test: a) standard Leclanché cell (natural ore), b) high-power Leclanché cell (electrolytic MnO_2), c) zinc chloride cell, d) alkaline manganese cell [1] (by permission of Arnold: C.A. Vincent, B. Scrosati, *Modern Batteries. An Introduction to Electrochemical Power Sources*, 2nd edition, Edward Arnold, London, 1997).

The zinc–mercuric oxide or Ruben–Mallory cell

which was introduced in 1940 and used in the first pacemakers, has been phased out from consumer applications and replaced by the zinc–silver oxide battery (first marketed by Union Carbide in 1961) for miniature portable electronics, as in watches and photographic equipment. This cell and its reaction may be written:

The zinc–silver oxide has a high energy density that can be delivered at relatively high current, and it has an extremely stable discharge voltage, a good shelf life and ability to operate over a wide temperature range. Large zinc–silver oxide cells are used in military and aerospace applications.

The zinc–air battery,

is a hybrid cell, i.e., one of the reagents is in the gas phase. This battery falls between the zinc systems above and fuel cells in which the reactants for both electrode reactions are continuously provided from external sources.

The zinc–air primary button cell has the highest specific energy of all consumer cells (Figure 4, above) due to the oxygen cathode's low weight and infinite capacity. Thus, the button-type zinc–air cell accounts for almost 95 % of the hearing-aid market, although it is also of interest because its chemistry, like that of the alkaline manganese system, is the basis for the rechargeable cell described in Section 2.2.3 under “Zn-based systems”.

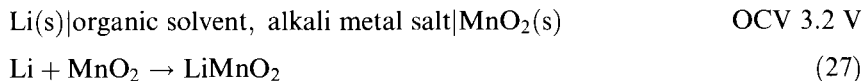

Lithium-based systems

Its high specific capacity (3862 Ah kg^{-1}) and markedly negative redox potential make lithium very attractive as a negative electrode, although its high reactivity can be a drawback. There are three types of lithium primary cells, depending on the type of cathode. For the latter are employed materials that are insoluble in the electrolyte, such as polycarbon fluorides, sulfides, and metal oxides; those that completely dissolve in the electrolyte, such as SO_2 ; or liquids, such as SOCl_2 . The lithium-based systems are lightweight, high-performance power sources for applications in miniaturized apparatus. For example, primary lithium batteries substituted for zinc–mercuric oxide cells in powering pacemakers: the first lithium/iodine-poly(2-vinylpyridine) (PVP) battery was implanted in Italy in 1972 [7] and since then over five million lithium/iodine PVP batteries have been implanted. This is a solid-state battery in which the anode is lithium metal and the cathode is an iodine charge transfer complex formed by combining a poly(2-vinylpyridine) donor and iodine acceptor. By making direct contact between anode and cathode, a thin layer of lithium iodide, which acts as a solid electrolyte, is formed. The cell and reaction are:

Cell discharge is accompanied by the migration of lithium ions from the anode to the cathode. As the discharge progresses, further LiI forms at the cathodic side of the electrolyte and the internal resistance of the cell rises; this is the main disadvantage of this system [8].

Lithium batteries with a manganese dioxide cathode are also used when reduction in size and weight is important, such as for powering 35 mm flash cameras. The lithium–manganese dioxide cell and reaction may be written as:

2.3.2 Secondary Cells

Figure 6 shows a comparison of practical energy density and specific energy of rechargeable batteries. It is worth noting that there is an increasing energy storage

Figure 6. Practical energy density and specific energy of various rechargeable batteries.

capability per mass or volume unit when going from the lead–acid to the lithium–metal systems due to the lithium’s high specific capacity and negative redox potential.

Lead-acid system

The characteristic of the lead–acid battery is that both electrodes are based on the chemistry of lead. The discharge–charge process is known as the double sulfate reaction, with the positive and negative electrodes being the seats of a dissolving–precipitating (and not some kind of solid-state ion transport or film formation) mechanism of the lead sulfate. The cell, the electrode reactions and the cell reaction are:

During discharge sulfuric acid is consumed and water is formed: this strongly affects the OCV, which depends on the electrolyte activity in solution and, consequently, on the state of charge (Figure 7). During discharge the formation of lead sulfate passivates both electrodes and reduces the practical capacity, and during charge lead sulfate is reconverted to Pb and PbO₂. The energy efficiency of charge–discharge is

Figure 7. OCV and electrolyte density as a function of the percentage of discharge capacity for the lead-acid cell [1] (by permission of Arnold: C.A. Vincent, B. Scrosati, *Modern Batteries. An Introduction to Electrochemical Power Sources*, 2nd edition, Edward Arnold, London, 1997).

affected by such side reactions as the evolution of oxygen at the positive electrode during charging, when the cell approaches 85–90 % full charge, and the evolution of hydrogen at the negative electrode during overcharge, causing water loss [9].

Today the main use of lead-acid batteries is in vehicle SLI applications. Most vehicles use a 12 V battery with a capacity in the range 40–60 Ah. The lead-acid battery is also in industrial service for traction and stationary purposes, and it has also been tested in electric vehicles. Lead-acid battery technology was developed at the end of the 19th century: the basic chemistry and operating principles have remained unchanged, but continuous improvements have rendered the battery more suited to market demands. The rate of progress in the last 40 years has increased and automotive batteries are now of either low-maintenance or maintenance-free design. It is also worth noting that valve-regulated lead-acid batteries (VRLA) were introduced to minimize water loss by promoting the chemical recombination of the oxygen at the negative electrode. In the early 1990s the VRLA batteries were considered for electric vehicle applications because of their favorable cost and specific power characteristics [10]. Some of the most recent advances in lead-acid battery design are thinner electrodes, based on woven Pb-coated fiberglass grids, which are cut into bipolar plates horizontally stacked, and new separator/acid-retention systems. Whilst all of these are materials and manufacturing improvements, the engineering of the charging systems has also increased cycle life fourfold and improved active-material utilization [10, 11].

Ni-based systems

The nickel-cadmium battery is the most popular alkaline secondary battery. The cell and its reaction are:

The negative electrode active material is cadmium, the positive one is nickel oxyhydroxide, and their preparation involves different components and methods [9]. During discharge, the cadmium is oxidized to form cadmium hydroxide and trivalent nickel hydroxide is reduced to divalent nickel hydroxide, with water consumption. This type of battery is available in several cell designs and a wide range of sizes. The sealed cells are important in the consumer electronics market in portable cordless appliances, as well as in defense and aerospace applications (in 1964 the first prismatic nickel–cadmium cell flew on *Explorer 23*). Nickel–cadmium cells are characterized by a long cycle life, relatively high rates of charge and discharge, an almost constant discharge voltage and the ability to operate at low temperatures. However, the cost of nickel–cadmium cell construction, higher than that of lead–acid, and the health risks associated with the manipulation of cadmium have spurred the search for alternative systems.

Another interesting nickel-based system is the nickel–hydrogen cell, a hybrid system similar to the zinc–air primary cell described in Section 2.3.1, under “Zn-based systems”. The cell and its reaction are:

Developed in the 1960s, it makes use of different technologies for its electrodes: NiO(OH) is from nickel–cadmium and H₂ from fuel-cell systems. Because of its longer cycle life the main use of the nickel–hydrogen battery is in aerospace applications to replace the nickel–cadmium cells. For example, the Hubble Space Telescope launched in 1990 was equipped with nickel–hydrogen cells [12].

Combining the nickel–cadmium and nickel–hydrogen systems technologies has given rise to the nickel–metal hydride rechargeable battery, one of the most advanced rechargeable systems commercially available and an environmentally friendlier alternative to nickel–cadmium batteries. The cell and its reaction may be written:

New, high-density nickel oxide electrode materials, coupled with nonwoven nickel-fiber current collectors, have significantly improved the performance of the nickel electrode even in the nickel–cadmium cells [5]. The alloys used to form hydride, which capture and release hydrogen in volumes up to nearly a thousand times their own, include rare-earth/nickel alloys (generally based on LaNi₅ and called AB₅)

Figure 8. Discharge curves at C/5 of same-size nickel–cadmium and nickel–metal hydride cells at 20 °C (by permission of National/Panasonic).

and titanium or zirconium/manganese alloys (TiMn_2 , ZrMn_2 generally called AB_2). Metal hydride electrodes are made by mixing the alloy powder with a binder and by applying the mixture to a metal foil or a nickel foam substrate [13]. The optimization of this battery is continuously in progress and, as a consequence of the similarity between the nickel–metal hydride and the nickel–cadmium cells, the achievements in the former may be a benefit also for the latter: examples are the development of lightweight $\text{NiO}(\text{OH})$ electrodes (foams), the use of thinner separators, and increasing the packing efficiency of the active material for both the cadmium and metal hydride electrodes by decreasing the pore volume of the respective electrodes. Figure 8 shows a comparison of the performance of nickel–cadmium and of nickel–metal hydride cells. In the case of the nickel–metal hydride system extensive research is also under way to develop new multicomponent, multiphase alloys, to meet such demands as high hydrogen storage capacity, strength of the metal–hydrogen bond, oxidation and corrosion resistance, fast gas recombination kinetics, and reliability at low cost [14]. The nickel-based systems have also benefited from the advent of the power management concept developed for lithium-ion batteries. The circuitry (sometimes incorporated into the battery package) and software developed to allow the exchange of information between the battery and the charging device has greatly enhanced safety and improved cycle life.

The major issues to be solved for nickel–metal hydride batteries are the temperature control during charge (damage occurs if the cell operates at $T > 65^\circ\text{C}$), the high self-discharge (15 % in two days at 38°C), and cell cost. Nevertheless, efforts to develop nickel–metal hydride batteries for use in electric vehicles have even led several automotive companies to offer models powered by this type of battery [14].

Zn-based systems

Although the rechargeable alkaline Zn-MnO_2 batteries are not performance-competitive with the nickel–cadmium batteries [15], they are midway between a

low-cost alternative to rechargeable systems and a cheaper option to the continuous replacement of primary cells. The modification of the internal design of the primary alkaline cell produces a lowering of the capacity of the rechargeable version; nevertheless, the rechargeable alkaline Zn–MnO₂ batteries may be used instead of the primary alkaline cells in applications requiring frequent battery replacement because they can be recharged at least 25 times before being discarded.

Another zinc-based system is the zinc–nickel one, whose key advantages include high voltage, high energy density, good high-rate discharge characteristics, and low cost. The cell and its reaction may be written:

although the main oxidation product of zinc is probably the Zn(OH)₄^{2−} ion. One drawback is poor cycle life, which is mainly due to the morphology of the electrodeposited zinc: dendritic deposits may provoke a short circuit by penetrating through the separator and spongy, loosely adherent deposits reduce capacity. Moreover, electrode shape changes may occur on cycling, as dissolution and re-deposition of the zinc do not take place at the same location and to the same extent and morphology. Alternative zinc electrode designs have been proposed to better the performance of this system, including the use of metallic foam collectors and special conductive additives, coupled with improved NiO(OH) electrodes, to make it competitive with the nickel–cadmium system [16–18].

The zinc–air system has become rechargeable during the last 20 years [19]. The cell and its reaction are:

Several methods have been examined to upgrade the quality of the zinc deposit, such as electrolyte circulation, electrode vibration, and air bubbling to disturb the diffusion layer. New and special porous, highly hydrophobic and electrically conductive modified carbon catalysts are under study to improve the lifetime of the air electrode. The behavior of the electrocatalyst during recharge, when it is necessary to apply high anodic voltages, remains indeed one of the major drawbacks. Nevertheless, since 1997 a zinc–air battery has been manufactured and tested in vehicles as “mechanically rechargeable” cells: at special charging stations, the oxidized zinc electrode will be removed from the cell and a fresh one put in, more or less in the same time it takes to fill up a conventional car. The exhausted zinc electrodes are then put in a separate electrochemical cell and recharged against an inert electrode [20].

Table 2. EV battery performance goals set by USABC.

Parameter	Mid-term target	Long-term target
Life [cycles]	600	1000
Life [years]	5	10
Piece cost [\$ kWh ⁻¹]	150	100
Mass [kg]	500	200
Volume [L]	296	133
Recharge time [hours from 80 % DOD]	6	3
Self-discharge [%]	15 ^a	15 ^b
Specific peak power [W kg ⁻¹]	150	400
Power density [W L ⁻¹]	135	600
Energy density [Wh L ⁻¹]	135	300
Specific energy [Wh kg ⁻¹]	80	200

^a in 48h, ^b in 1 month.

Applications in electric vehicle technology

To conclude this section and as a prolog to Section 2.4 on advanced lithium rechargeable batteries, a few additional words on the applications of rechargeable batteries in electric vehicle (EV) technology are in order. The pressing need to come up with solutions to the problem of urban pollution has increased research efforts in battery systems for zero-emission vehicles, especially in regard to achieving the technological breakthrough enabling such vehicles to attain the performance characteristics of acceleration and range that are comparable with those of today's conventionally powered cars.

As mentioned in Section 2.1, the USABC, which involves the US Department of Energy (DOE), the Electric Power Research Institute (EPRI), and the three car manufacturers Daimler–Chrysler, Ford, and General Motors, set the targets for battery application in EV in terms of practical specific energy, specific power, and cycle life (Table 2). The goals of the USABC are to develop electrical energy systems for EV having performance competitive to gasoline-powered vehicles: meeting the mid-term goals would allow the expansion of the market, while achieving the long-term ones would allow EV to be competitive with internal-combustion vehicles.

In a typical electric car a specific power of 400 W kg⁻¹ and a specific energy of 200 Wh kg⁻¹ would mean that it is possible to achieve 0–60 mph (0–96 km h⁻¹) acceleration in 9 s with a range of 200 miles (320 km) in standard driving conditions. A lifetime of 10 years at a cost of \$100 per kWh would mean that a \$4000 battery could be amortized over 10 years.

Many projects have taken off in the USA, Japan, and Europe involving governmental agencies, universities, and battery and car companies [21]. The projects are focused on achieving both the mid-term and long-term goals mainly by developing nickel–metal hydride systems and lithium-based technologies. Energy and power targets, which determine range and acceleration, appear to be within reach, although challenges remain in cycle life, battery cost, and manufacturing. To cut costs, proj-

ects are focusing on three key areas: raw materials (by lowering material costs or using materials more effectively), battery design (small and lighter batteries lead to enhanced vehicle performance), and mass manufacturing (most of these batteries never have been made in quantity and new production techniques will have to be adopted).

2.3.3 Supercapacitors

Supercapacitors are devices for high-power applications: they provide a higher power density than batteries and, despite their lower operating voltage, a higher energy density than conventional dielectric capacitors because of the high capacitance of their electrode materials. By the 1970s, a mere decade after industrial research into these devices began in earnest, high-performance supercapacitors were developed both for military systems, which largely demand short and intense bursts of power, and computer memory backup systems, which demand a power supply that is less intense but more steadily extended over time. The increasing interest in these devices has also been stimulated by their potential application as power systems operating in parallel with battery system in electric vehicles [22, 23]: the supercapacitor will deliver peak pulses of power for acceleration and be recharged by the battery during deceleration and braking.

Two types of supercapacitors are currently being investigated: the double-layer and the redox. The former is not based on an electron transfer process: its capacitance, electrostatic in origin, arises from the separation of electronic and ionic charges at the interface between high-specific-area (up to $2500 \text{ m}^2 \text{ g}^{-1}$) carbon electrodes and the electrolyte solution. In the latter, faradaic charge transfer processes take place at the electrode materials, as in a battery, and produce what is called pseudocapacitance [24, 25]. Nevertheless, the research objectives are the same for double-layer and redox supercapacitors: to develop electrode materials with both high specific capacitance (gravimetric [F g^{-1}] and volumetric [F cm^{-3}]) to maximize energy storage and with low electrical resistance to maximize power. Electrode materials must be stable to assure long life of the device and have a high performance-to-cost ratio. The electrolyte in supercapacitors should ideally have a high breakdown voltage for greater energy storage and low electrical resistance for greater power. Low-resistance aqueous electrolytes lead to devices with good power but whose energy storage is limited by a decomposition voltage of about 1 V. Since organic electrolytes break down over 3 V, energy increases up to about one order of magnitude, given its dependence on the square of the voltage. Yet, at the same time, these electrolytes limit power because of their higher resistance. Two classes of electrode materials for redox supercapacitors are under study: metal oxides and conducting polymers [26].

Among the metal oxide pseudocapacitive materials the most representative are the crystalline ruthenium oxide RuO_2 [24] and the amorphous hydrous ruthenium oxide $\text{RuO}_2 \cdot x\text{H}_2\text{O}$ [27, 28], although other materials are under study, for example cobalt oxide [29] and vanadium oxide [30] xerogels, molybdenum-based materials [31, 32], and Ti–V–W–O oxides [33].

RuO_2 films are yielded in situ by thermal (300–500 °C) decomposition and oxidation of a $\text{RuCl}_3 \cdot x\text{H}_2\text{O}$, whose solution in water or alcohol is previously dipped in or sprayed onto the Ti substrate. The properties of the oxide depend significantly on the preparation temperature. A $\text{RuO}_2 \cdot x\text{H}_2\text{O}$ electrode can be prepared by pressing on Pt mesh a mixture of $\text{RuO}_2 \cdot x\text{H}_2\text{O}$ powder, produced by aqueous sol-gel, and a binder. This sol-gel preparation method yields a material with a capacitance value (760 F g⁻¹) higher than the highest value reported for RuO_2 (380 F g⁻¹) [34–36].

It has been demonstrated that by starting from hydrogenated hydrous ruthenium oxide $\text{HRuO}_2 \cdot x\text{H}_2\text{O}$ (obtained using either an electrochemical or a chemical method from $\text{RuO}_2 \cdot x\text{H}_2\text{O}$ powder) the charge-discharge efficiency is improved ($\eta > 0.9$) from the first cycle, with power and energy density maintained through the cycles. Starting from $\text{RuO}_2 \cdot x\text{H}_2\text{O}$, indeed, results in O_2 evolution and water loss in the first few cycles which damage the cell by reducing the cell performance [34]. The electrochemical reaction for an $\text{HRuO}_2 \cdot x\text{H}_2\text{O}$ -based supercapacitor, when a faradaic current flows through the electrode materials, may be written:

where $0 < \delta < 1$. The positive and negative electrodes are $\text{HRuO}_2 \cdot x\text{H}_2\text{O}$ in the discharged state, and $\text{RuO}_2 \cdot x\text{H}_2\text{O}$ and $\text{H}_2\text{RuO}_2 \cdot x\text{H}_2\text{O}$, respectively, in the fully charged state.

The other materials being investigated for redox supercapacitors are the conducting polymers. In the early 1980s there was much enthusiasm for flexible lithium-polymer cells that use conducting polymers as positive electrodes [37–39]. After a charge transfer process named the doping process, such organic polymers as polypyrrole, polythiophene, and polyaniline, characterized by an extended π -electron delocalization, become conductive. The reactions (37) and (38) show the polythiophene p- and n-doping processes respectively, i.e., the process in which the polymer is oxidized and becomes positively charged, and that in which the polymer is reduced and becomes negatively charged. The doping-undoping, i.e., the charging-discharging process, of the conducting polymers is associated with the insertion-release of the counterions (A^- and C^+) coming from the electrolyte to balance the injected charge; thus the conducting polymers may also be depicted as ion insertion materials [40].

Conducting polymers are used in both aqueous and organic electrolytes in different combinations to yield different types of supercapacitors [41–44] whose storage–charge capacity and operating potential range increase depending on type. The three types are: I) a symmetric supercapacitor in which a p-dopable polymer is the active material on both electrodes; II) an unsymmetric supercapacitor based on two p-dopable polymers selected by virtue of the difference in potential ranges over which they become p-doped; and III) a symmetric or unsymmetric supercapacitor based on p- and n-dopable polymers. In the completely charged state Type I has one polymer electrode in the fully p-doped form and the other one in the undoped form; the cell voltage is typically 1 V. Since in the completely discharged supercapacitor both polymer electrodes are at a half p-doped state, only half of the polymer's total p-doping charge can be delivered by the operating supercapacitor. In the completely charged state Type II has the polymer of the positive electrode in the fully p-doped state and that of the negative electrode in the undoped state and, when this device is discharged, the polymers of both electrodes are partially p-doped. The charge involved in this type of supercapacitor is greater than that of Type I and the operating potential can reach 1.5 V because it is related to the difference between the p-doping potential domains of the two polymers. In the fully discharged state Type III has both electrodes in the undoped states, whereas in the charged state one electrode is p-doped and the other n-doped, according to reaction (39) for a symmetric device, i.e., when the same p- and n-dopable polymer is used for both electrodes.

The advantage of the Type III configuration is that all the doping charge is delivered by the supercapacitor at high potential, up to 3 V, because of the separation between p- and n-doping potential domains, a separation which is related to the polymer energy gap between conduction and valence bands, when the supercapacitor is symmetric. Type III is thus the most promising in terms of energy density; it has a further advantage over Types I and II in that the charged supercapacitor has both electrodes in the doped state, i.e., in the conducting state, and the instantaneous power density is greater [45, 46]. Operating potentials such as 3 V are attainable only in organic electrolytes, and electrolyte optimization, even in terms of salt concentration, is an important target since in Type III supercapacitors, as in double-layer ones, salt consumption occurs during device charge (see reaction (39)).

Figure 9 shows the discharge curves of a Type I polypyrrole-based, a Type II polypyrrole/poly(3-methylthiophene)-based and a Type III poly(dithieno[3,4-*b*;3',4'-*d*]thiophene)-based supercapacitor at 4 mA cm⁻² discharge current. Types I and II can be assembled using such conventional heterocyclic polymers as polypyrrole, polyaniline and polythiophene, which are efficiently p-dopable polymers and can easily be chemically or electrochemically synthesized from inexpensive

Figure 9. Discharge curves at 4 mA cm^{-2} of the three types of supercapacitors: a) polypyrrole/ LiClO_4 -propylene carbonate (PC)/polypyrrole; b) polypyrrole/ LiClO_4 -PC/poly(3-methylthiophene); c) poly(dithieno[3,4-*b*:3',4'-*d*]thiophene)/ $(\text{C}_2\text{H}_5)_4\text{NBF}_4$ -PC/poly(dithieno[3,4-*b*:3',4'-*d*]thiophene), potentiostatically charged at 1.1 V, 1.15 V, and 3.0 V, respectively.

commercially available monomers. By contrast, the very negative potentials required for n-doping of conventional conjugated polymers, such as polythiophene, make the n-doping a process that requires high-quality electrolytes with very negative breakdown cathodic voltages and a controlled working atmosphere. New materials featuring n-doping at less negative potentials than that of polythiophene have been developed, although the molecular weight of their monomer units is usually significantly higher than that of polythiophene [47, 48]; thus higher doping level values are required for these new materials to reach a high specific capacitance. However, achieving such high doping values involves significant mechanical stress, resulting from the large quantity of ions moving into and out of the polymer structure [49].

Recently, Type III supercapacitors based on conventional polymers have been investigated: symmetric and unsymmetric devices based on a poly(3-methylthiophene) negative electrode and a poly(3-methylthiophene) or polythiophene positive electrode show good cyclability performance to repeated charge-discharge cycles [50]. For a symmetric supercapacitor with composite electrodes prepared by mixing poly(3-methylthiophene), carbon, and binder, Figure 10(a) displays the delivered charge and the coulombic efficiency for 2000–5000 cycles at 5 mA cm^{-2} between 0 and 3.1 V; Figure 10(b) shows the supercapacitor and electrode potential profiles of the 2000th cycle.

Conducting polymers are promising electrode materials because the kinetics of the charge-discharge process, i.e., the doping-undoping, is generally fast; because

Figure 10. Symmetric supercapacitor with composite poly(3-methylthiophene)–carbon–binder electrodes. a) Delivered charge (■) and coulombic efficiency (○) of galvanostatic cycles (from 2000th to 5000th) at 5 mA cm⁻² between 0 and 3.1 V; b) potential profiles of supercapacitor (solid line), and of positive (broken line) and negative (dotted line) electrodes during the 2000th galvanostatic cycle.

the charge is stored through the volume of the material; and because they can usually be manufactured at a cost that is significantly lower than that of metal oxides such as ruthenium oxides and comparable with that of activated carbons, which at present are the only ones on the market [51].

The distinction between a polymer-based supercapacitor and a polymer-based battery is not very sharp. In the early 1980s Kaneto et al. [52] proposed a polythiophene-based battery in which the electrodes become p- and n-doped upon charge, and undoped upon discharge. A criterion that can be used to distinguish batteries and supercapacitors might be the function they are expected to fulfill in terms of specific energy and power, as the Ragone plot of Figure 11 shows. A supercapacitor is required to deliver a high specific power for a short period (10–30 s), whereas the energy is significantly lower than that of conventional and advanced batteries and fuel cells.

Figure 11. Ragone plot of some electrochemical energy conversion systems.

2.3.4 Fuel Cells

Although a fuel cell operates like a battery, it does not run down or require re-charging from an external electric source, since electric energy is produced so long as fuel is supplied. The hydrogen (or other fuel) continuously flows into the anode and the oxygen (or air) into the cathode: the chemical energy of the cell reaction, which is the sum of the charge transfer reactions at the two electrodes, is converted into electrical energy with the production of water, as Figure 12 shows [53].

The idea of producing electric energy from hydrogen and oxygen, without Carnot limitations and with water as by-product, has been pursued since the 19th century. The first hydrogen–oxygen fuel cells were developed in the 1840s by Grove, who already recognized the need for proper contact of the gas, electrolyte, and solid electrode phases. This so-called three-phase interface is still an issue today, and its improvement is an important goal. In the early 1890s coal was envisioned as fuel, and in 1899, after the discovery of solid oxide electrolytes, the ceramic fuel cell was conceived. A century after Grove, Bacon began work on hydrogen–oxygen forerunners of the modern fuel cells and, by controlling the porosity of the electrodes, optimized the three-phase interface area, greatly increasing the performance of alkaline cells.

Advances in fuel cells were later accelerated by space and defense programs. Fuel cells found initial practical application with the Gemini (1962–1966) and the Apollo (1968–1972) spacecraft missions, and are still used to provide water and electricity for the Space Shuttle. The upgrade in fuel cell performance over the last four decades has been based on the development of new proton-conducting polymers, like Nafion™ and Gore-tex™, ceramics and catalysts, as well as on greater insights into

Figure 12. Phosphoric acid fuel cell (PAFC).

the electrochemistry of surface reactions and transport processes within porous systems [54, 55].

The fuel cell electrode reactions are catalyzed by different materials in different temperature ranges. A classification of the fuel cells can be made on the basis of the electrolyte, which in turn determines the operating temperature and, with it, the catalysts to be applied in the electrodes. The electrode reactions that take place in the different types of fuel cells are summarized in Table 3, which also lists the electrolytes and operating temperatures [56].

The solid oxide fuel cells (SOFCs) use porous electrodes and hard ceramic electrolyte, the latter generally being yttria-stabilized zirconia (YSZ) to enable oxygen ions to move from cathode to anode, and they operate at 1000 °C [57, 58]. The molten carbonate fuel cells (MCFCs) work with mixed lithium and potassium carbonate as electrolyte at 650 °C [59, 60]. Both MCFCs and SOFCs can be fed with natural gas: the heat required to sustain the endothermic reforming of low-molecular-weight hydrocarbons can be provided by the electrochemical process, which has led to various internal reforming concepts [61]. The high-temperature fuel cells are very promising, especially for large-scale (0.1–1 MW) power generation [62–64], although small tubular SOFCs fed with biogas are under study [65].

The electrolyte in the phosphoric acid fuel cells (PAFCs), which operate at 200 °C, is phosphoric acid and the electrodes are carbon black or graphite plates in which Pt particles are dispersed. The PAFCs are generally fed by natural gas, and CO has to be removed (only a 1 % concentration is accepted) to avoid Pt poisoning. PAFCs are mainly used for combined heat and power generation (up to 200 kW) in

Table 3. Different types of fuel cells, electrode reactions and operating temperatures.

Type	Electrolyte	Anodic reaction	Cathodic reaction	$T [^{\circ}\text{C}]$
SOFC	solid oxide	$\text{H}_2 + \text{O}^{2-} \rightarrow \text{H}_2\text{O} + 2\text{e}^-$	$1/2\text{O}_2 + 2\text{e}^- \rightarrow \text{O}^{2-}$	1000
MCFC	molten carbonate	$\text{H}_2 + \text{CO}_3^{2-} \rightarrow \text{H}_2\text{O} + \text{CO}_2 + 2\text{e}^-$	$1/2\text{O}_2 + \text{CO}_2 + 2\text{e}^- \rightarrow \text{CO}_3^{2-}$	650
PAFC	phosphoric acid	$\text{H}_2 \rightarrow 2\text{H}^+ + 2\text{e}^-$	$1/2\text{O}_2 + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{H}_2\text{O}$	200
AFC	alkaline	$\text{H}_2 + 2\text{OH}^- \rightarrow 2\text{H}_2\text{O} + 2\text{e}^-$	$1/2\text{O}_2 + \text{H}_2\text{O} + 2\text{e}^- \rightarrow 2\text{OH}^-$	80–100
PEFC	polymer electrolyte	$\text{H}_2 \rightarrow 2\text{H}^+ + 2\text{e}^-$	$1/2\text{O}_2 + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{H}_2\text{O}$	80–100
DMFC	polymer electrolyte	$\text{CH}_3\text{OH} + \text{H}_2\text{O} \rightarrow \text{CO}_2 + 6\text{H}^+ + 6\text{e}^-$	$1/2\text{O}_2 + 2\text{H}^+ + 2\text{e}^- \rightarrow \text{H}_2\text{O}$	80

industry and hospitals [66]; a 200 kW natural gas, fuel cell, stationary power plant is a commercial product (PC25™) from IFC/ONSI [67]. Alkaline fuel cells (AFCs) use alkaline potassium hydroxide as the electrolyte and operate at a lower temperature (80–100 °C) than PAFCs. Long used by NASA on space missions, the AFCs are based on a mature technology, but their high cost and their sensitivity to CO₂ (such that hydrogen and CO₂-free air are required) limit their applications for civilian uses [68].

Polymer electrolyte fuel cells (PEFCs), also called polymer electrolyte membrane fuel cells (PEMFCs) [69], are used at low temperature (they heat themselves to a working temperature of 80–100 °C). The electrolyte is a 100 μm membrane such as Nafion™, able to exchange protons. Porous electrodes are made by depositing electrocatalytic materials (Pt or Pt compounds) on carbon-based substrate. To avoid catalyst poisoning by CO, the fuel has to be pure hydrogen, which is further treated to reduce the CO content to less than 100 ppm. The use of Pt increases the cost of PEFCs, and the CO poisoning and water management represent key problems [70]. According to the US Department of Energy, PEFCs are candidates for light-duty applications both in stationary systems [71, 72] and in vehicles: several car manufacturers have started developing cars powered by fuel cells (the first, NeCar I, was developed in 1994 by Daimler-Benz, which is already aiming at large-scale production of fuel-cell-powered vehicles) [73–75]. Another feature of PEFCs is that they can be directly fed by methanol: direct methanol fuel cells (DMFCs) eliminate the need for reforming the fuel because the methanol is oxidized directly at the anode. This type of fuel cell typically operates in the 60–90 °C temperature range [76].

In future, closed-loop power generation looms on the horizon, and studies on regenerative fuel cells have already begun [77]. The water could be electrolyzed into hydrogen and oxygen by a solar-powered system, the hydrogen and oxygen would generate electricity and water, the latter would be recycled back to the solar electrolyzer and the process would then restart.

2.4 Lithium Rechargeable Batteries

The most promising battery for electric vehicle applications is the lithium battery. Lithium is a promising negative electrode material because it is the lightest of all metals and has the lowest standard redox potential. Batteries based on lithium chemistry have the highest specific energy and energy density of all chemical types (Figure 6), so it is not surprising that the first studies on lithium rechargeable batteries were devoted to electric vehicle applications. Recently, the field of application of this battery has moved toward the growing consumer market and lithium battery technology is fast being developed to provide power to portable devices under the most demanding conditions. These applications require batteries of small dimensions and long life, high cell voltage, design versatility, and good performance-to-cost ratio, and that can operate in a wide temperature range.

There are two main kinds of rechargeable battery based on lithium chemistry: the lithium-metal and the lithium-ion battery. In both the positive electrode is a lithium insertion material; the negative in the former is lithium metal and in the latter it is a lithium insertion host. The reason for the application in lithium batteries of insertion electrode materials, which are electronic and ionic conductive solid matrixes (inorganic and carbon-based), is that electrochemical insertion reactions are intrinsically simple and highly reversible.

The cell, and the electrode and cell reactions, for the lithium-metal battery are:

and for the lithium-ion battery:

Figures 13 and 14 display the discharge processes for the two kinds of lithium battery. During discharge at the anode the lithium ions are formed from the lithium metal or are released from an $\text{Li}_x\text{A}'_{y'}\text{B}'_{z'}$ host material; at the cathode the lithium ions are inserted into the void spaces of the structure of the A_yB_z insertion material. The lithium-ion battery behaves almost like a concentration cell: lithium ions move from a lithium-rich source toward the cathode, which acts as sink, while electrons flow through the external circuit from anode to the cathode.

This section will provide a general description of the lithium-metal battery, especially with regard to the problems arising from the use of lithium metal, and introduce the lithium-polymer batteries as a reliable solution to problems deriving from the use of the lithium-metal electrode. The lithium-ion battery will then be taken up and particular emphasis will be given to the insertion electrode materials used in both the lithium-metal and the lithium-ion batteries.

2.4.1 Lithium-Metal Batteries

The high theoretical specific capacity (3862 Ah kg^{-1}) and capacity density (2047 Ah L^{-1}) of the lithium-metal electrode, together with its promising redox potential, give the battery unique advantages in terms of specific energy and energy density.

Figure 13. Lithium-metal battery under discharge.

Figure 14. Lithium-ion battery under discharge.

On the other hand the high reactivity of lithium metal gives some problems for its application as the negative electrode in rechargeable configurations.

The strong reducing power of lithium metal makes it highly unstable in most known battery electrolytes. In some media, spontaneous chemical reactions yield passivating films of electrolyte decomposition products that cover the lithium surface and protect it from further corrosion. This surface layer is made up of various organic and inorganic compounds deriving from the reaction of lithium with the solvent, the salt, and impurities, and acts as an electronic insulator and ionic conductor, i.e., as a sieve that is permeable only to the lithium ion [78]. The composition and morphology of lithium passivating film depend on the kind of electrolyte used, and it is possible to obtain a composite or a stratified film structure [79].

The surface layer formation is a crucial phenomenon as it affects the electrode charge transfer rate. Low-conductivity films determine high electrode overvoltages and lower battery performance. The charge transfer resistance can be monitored by impedance spectroscopy measurements, which represent a useful tool for the in-situ characterization of resistive and capacitive processes occurring in different time scales (1 mHz–100 kHz) [80].

Charge–discharge of the lithium electrode means lithium deposition–dissolution, and repeated charge–discharge cycles can result in dendrite formation—a buildup of surface irregularities on the lithium electrode—promoted by surface nonhomogeneity resulting from the lithium–electrolyte interaction. Dendrites can grow to such an extent that they penetrate the separator between positive and negative electrodes and create an internal short circuit. At best, this phenomenon shortens the useful life of a rechargeable lithium-metal battery to 400 cycles or less. At worst, an internal short circuit could cause the battery's internal temperature to rise above the melting point of lithium (181 °C), which could cause severe flaming. Several publications on lithium-metal battery safety tests are available in literature, and the Tadiran Battery Division (Israel) proposed an intrinsically safe device, based on an electrolyte which is stable at low-to-medium temperatures and which polymerizes at temperatures over 125 °C, thereby protecting the cell from short circuit, overcharge and thermal runaway; this electrolyte also showed good compatibility with lithium metal in terms of interface resistance [81].

Many kinds of electrolytes [82, 83] and electrolyte additives, e.g., CO₂ [84], have been investigated in the pursuit of compact and uniform passivation layers for a stable lithium interface resistance, and a smooth lithium surface so as to control dendritic deposition. The high reactivity of lithium to the electrolyte, the related corrosion phenomena, and dendrite formation all contribute to lowering the coulombic efficiency of the charge–discharge process and are detrimental to the battery's cycle life. Hence, to ensure a sufficiently high number of charge–discharge cycles, an amount of lithium in excess of the stoichiometric quantity is needed (Figure 15), although this lowers the specific energy of the battery.

As mentioned above, several strategies have been pursued to improve the rechargeability and reliability of the lithium-metal electrode. One of the most promising, and different, approaches in this connection consists of replacing the liquid electrolyte with a polymer electrolyte. First introduced by Armand in the early

Figure 15. Number of cycles the battery can sustain at different values of lithium excess with respect to the stoichiometric one (Q_E/Q_S) as a function of the efficiency of the lithium deposition–stripping process.

1970s [85], polymer electrolytes typically involve a lithium salt Li^+X^- dissolved in a high-molecular-weight dry polymer such as poly(ethylene oxide) (PEO) [86–88].

Lithium–Polymer Batteries

The substitution of the liquid electrolyte with the less reactive polymer electrolyte has led to lithium–polymer batteries, among the most likely to be commercialized for electric vehicles [89]. It must be stressed that the lithium–polymer battery is still a lithium–metal battery and not a lithium-ion one. Lithium–polymer batteries are solid-state, in that their electrolyte is a solid. A great safety advantage of this type of battery is that the electrolyte will not leak out if there is a rupture in the battery case. Furthermore, it can be assembled in any size and shape, allowing manufacturers considerable flexibility in cell design for electric vehicle or electronic equipment.

Because the conductivity of polymer electrolytes is generally low, thin batteries are assembled (50–200 μm) with electrolyte thickness ranging from 20 to 50 μm . Conventional polymer electrolytes based on PEO and lithium salts, owing to their high crystallinity, reach useful conductivity values only at temperatures above 60°C, i.e., above the melting temperature of the crystalline phase. If the low conductivity at room temperature prevents their application for consumer electronics, this does not represent an obstacle for electric vehicles, for which an operating temperature higher than that of the transition in the amorphous phase is expected.

This is not to say that considerable effort has not been devoted to the development of polymer electrolytes with high conductivity at room temperature. Two different approaches have been pursued:

- 1) polymer modification to reduce their crystallinity by crosslinking [90, 91], by adding pendent short PEO chains [92], by copolymerization [93], or by realization of interpenetrating networks [94]; and
- 2) design and synthesis of new lithium salts with bulky and polarizable anions like $\text{Li}[(\text{CF}_3\text{SO}_2)_2\text{N}]$ [95], which improve polymer conductivity at all temperatures and slow down the crystallization rate.

However, it seems likely that a conductivity value of $10^{-3} \text{ S cm}^{-1}$ at room temperature is a goal that can only be achieved with polymer networks including organic solvents as plasticizers [96] or with polymer matrixes like polyacrylonitrile [97] or poly(methyl methacrylate) [98] entrapping a large amount of organic electrolytic solution, i.e., with “hybrid” and/or gel electrolytes. These electrolytes combine the advantage of the polymer’s mechanical properties with the electrochemical properties of the liquid electrolytes.

The strategy of hybrid and gel electrolytes is very promising for lithium-ion batteries, but it seems less viable for lithium-metal batteries due to the reactivity of lithium metal with the encapsulated solvent. In fact, high conductivity is not the only parameter in selecting a successful polymer electrolyte for the development of lithium batteries: a low interface resistance and a high interface stability over time are also required to assure good cyclability and long life.

Polymer electrolytes have been shown to stabilize the lithium/electrolyte interface, yielding stable and low interface resistance, especially when ceramic additives such as $\gamma\text{-LiAlO}_2$ are used. Furthermore, the $\gamma\text{-LiAlO}_2$ ceramic additive has been shown to stabilize the polymer amorphous phase and to slow down the recrystallization process [99–103]. Thus, the unique electrochemical performance of lithium metal can be applied in practical devices by substitution of the liquid electrolyte with a solid one whose conductivity and stability can be enhanced with ceramic additives.

2.4.2 Lithium-ion Batteries

To avoid the problems associated with lithium metal, lithium insertion materials (e.g., graphitic carbons) are being investigated as negative electrodes. With respect to lithium metal, the use of negative insertion materials improves the cycle life and safety of the battery but lowers the cell voltage, the theoretical specific capacity, and the charge transfer rate [104].

As Figure 14 shows, the combination of two lithium insertion materials (characterized by two different potentials of the lithium insertion process) yields a cell—the so-called “rocking chair battery”, after Armand [105] and Scrosati et al. [106]—in which during discharge lithium ions are released from the anode and travel through the electrolyte toward the cathode without variation in the composition of the

electrolyte. Here electrolyte volume can be minimized to reduce electrolyte ohmic drop and battery weight. When the lithium ions reach the cathode, they are incorporated into the insertion cathode material and the process is highly reversible.

Rechargeable lithium-ion batteries have OCV values up to 4.2 V, i.e., more than twice those of Ni–Cd and Ni–MH batteries, and the specific energies are more than 40 % higher. Lithium-ion batteries can also charge and discharge faster than lead–acid and Ni–MH batteries, and show long cycle life under normal operation because structural changes in the negative and positive electrodes caused by the insertion and removal of lithium ions are quite limited. It is thus not unexpected that with designers demanding smaller, lighter, and more powerful energy sources, lithium-ion batteries are rapidly replacing Ni–Cd and Ni–MH ones (Figure 3).

As with lead–acid and Ni–MH batteries, overcharging of lithium-ion batteries must be carefully controlled to prevent detrimental electrode or electrolyte decomposition. This is one of the problems that advanced battery management systems can obviate, thereby ensuring the safety of lithium-ion batteries even in extreme conditions [107].

The first lithium-ion batteries were based on liquid electrolyte and in 1990 Sony commercially introduced for the consumer electronics market the first rechargeable lithium-ion battery based on a lithium cobalt oxide as the positive electrode and carbon as the negative one [108]. The development of lithium-ion batteries has rapidly increased since then and today much research is focused on plastic lithium-ion batteries in which the separator is a polymer membrane capable of adsorbing a large amount of liquid electrolyte, i.e., a gel electrolyte. The high mechanical stability and flexibility of these membranes enable simple manufacture of thin electrolyte films so that plastic lithium-ion batteries are at the cutting edge of rechargeable battery technology for cell size, easy packaging format, safety, and low cost. Bellcore Laboratories in the USA developed a successful technology to produce cells by laminating the electrode material on a membrane separator formed by a copolymer of vinylidene fluoride and hexafluoropropylene [109]. Replacing the cobalt-oxide-based positive electrode with cheaper insertion materials lowers lithium-ion battery costs. Ultralife Batteries Inc. is a company which has pursued this strategy and has developed a plastic lithium-ion battery with a manganese-oxide-based positive electrode. This battery has specific energy and energy density at the 1 C rate exceeding 120 Wh kg^{−1} and 200 Wh L^{−1}, respectively, and retains 90 % of initial capacity for 500 cycles at room temperature [110].

2.4.3 Insertion Electrode Materials

As reported above, lithium–metal and lithium-ion batteries are based on reversible lithium insertion, which takes place during charge–discharge processes of the positive electrode (and of the negative one for the rocking chair batteries) [111]. According to McKinnon and Haering [112], the reversible insertion of guest atoms into host solids, provided the host structure is not significantly altered during the process, is called intercalation, a special case of the insertion process.

Figure 16. Typical potential regions for the insertion of lithium ions into various hosts.

From the position of two given host structures on a redox potential scale such as that in Figure 16 [1, 113, 114], it is possible to determine which material will act as positive electrode and which as negative. For cell design optimization, it has to be taken into account how the basic properties of insertion materials vary as to composition and temperature. For instance, it is useful to determine how the cell voltage depends on the kind of host matrix and the amount of inserted Li^+ .

The basic requirements for the application of insertion materials in batteries are as follows [115].

- 1) Large free energy of cell reaction to provide high cell voltage for high energy density. Since lithium batteries can have a cell voltage >4 V, a wide electrochemical window of the electrolyte for the cycle life of the device is important [116].
- 2) Wide compositional range, x , for high cell capacity.
- 3) High diffusivity of lithium into the host matrix to enable high current density and high power density. Lithium diffusion into/from the host matrix is accompanied by a lithium concentration gradient across the insertion electrode, resulting in an electrode diffusion overvoltage [117]. The lithium ion transport into the electrode material depends on the type of void spaces available for lithium insertion, which can be one- (tunnel), two- (layer), or three-dimensional, such as those in Figure 17.
- 4) Minimal structural change as a function of composition to ensure good reversibility of the insertion process. The lithium insertion–deinsertion can determine volume changes in the host matrix, resulting in mechanical stress during charge–discharge cycles that in some cases can lead to irreversible cracks in the electrode

Figure 17. Schematic representation of lithium ion paths in insertion materials.

material (as with lithium alloys). In some cases insertion compounds can be thermodynamically unstable; for instance, the Jahn–Teller distortion of the LiMn_2O_4 spinel lowers the cyclability of this oxide [118]. There is no dearth of literature on the synthesis methods for controlling the structure, impurity, and phase impurity of the insertion materials. Such properties, which influence the electrochemical performance of the materials, were investigated via thermal analysis and by EXAFS, AFM, ASTM, SEM, and RX measurements [119–123].

- 5) Suitable electrode material morphology for enhanced electrochemical properties. Many laboratories are involved in the characterization of lithium insertion nanomaterials. Small particle size increases the lithium ion diffusion and can at times enhance insertion material capacity. For example, hard carbons with nanopores are high-capacity negative-electrode materials. Furthermore, as in the case of lithium alloys, nanoparticles lead to minor mechanical stress due to the volume variation during the insertion–deinsertion processes [124]. However, they also result in high surface area; hence the degradation due to the interactions with the solvent becomes more evident.
- 6) High electronic conductivity to obviate the need for additional conductive materials in the electrode. Additives are often used in composite electrodes to enhance conductivity, to act as binders, or as electrochemically inactive matrixes that attenuate the mechanical stress resulting from the volume variation of the insertion material during the insertion–deinsertion processes.
- 7) Insolubility in the electrolyte medium to eliminate self-discharge. Interactions with the electrolyte may cause irreversible capacity loss and coulombic efficiency values far from 100 %.

Positive Insertion Materials

Positive insertion materials can be based on transition metal oxides or chalcogenides; Table 4 lists the most investigated compounds [111, 120, 125].

The layered lithium insertion cobalt and nickel oxides are materials of industrial importance [126]. The layered structure provides two-dimensional paths for lithium insertion, during which a charge transfer occurs involving the reduction of M^{4+} to

Table 4. The most investigated positive insertion electrode materials.

Positive electrode material	Average electrode voltage [V vs. Li/Li ⁺]	Reversible range ^a [Δx]	Theoretical specific capacity ^a [Ah kg ⁻¹]
Li _x CoO ₂	3.9	0.5	137
Li _x NiO ₂	3.8	0.7	192
MnO ₂ (spinel)	4.0	0.5	154
LiMn ₂ O ₄ (spinel)	3.0	1	148
TiS ₂	2.1	1	239
MoS ₂	1.8	0.8	134
V ₂ O ₅	2.5	1	147

^athe theoretical specific capacity is based on a reversible range Δx of lithium content during the charge–discharge process: $\Delta x\text{Li}^+ + \Delta x\text{e}^- + \text{Li}_x\text{A}_y\text{B}_z \rightleftharpoons \text{Li}_{x+\Delta x}\text{A}_y\text{B}_z$

M³⁺ ions (M = Co, Ni). Diffusion of Li⁺ can result in the expansion of the host structure along the crystallographic *c*-direction.

The Li/Li_xCoO₂ cells exhibit a very high OCV in the 3.9–4.7 V range and a specific energy of ca. 1070 Wh kg⁻¹, based on an average discharge voltage of 3.9 V. At room temperature the lithium diffusion coefficient in LiCoO₂ ranges approximately from 10⁻¹¹ to 10⁻¹² m² s⁻¹, providing evidence for good lithium ion mobility. Reversible lithium insertion in Li_xCoO₂ takes place in a limited range of compositions because the highly oxidizing power of the almost delithiated Li_xCoO₂ causes oxidative decomposition of the electrolyte, with formation of detrimental films on the electrode surface [127].

LiNiO₂ is isostructural with LiCoO₂ and, having a redox potential slightly less positive than that of LiCoO₂, is less prone to electrolyte oxidation problems. Despite its excellent specific capacity (Table 4) and economic advantage over LiCoO₂, the nickel oxide has certain problems that have limited its wide application in practical cells. LiNiO₂ is quite difficult to prepare because of its tendency to form a nickel-rich nonstoichiometric phase which exhibits a lower electrochemical performance [128]. Furthermore, it has lower thermal and cycling stabilities with respect to cobalt oxide, although these can be improved with certain synthesis methods [129]. LiNiO₂ shows an irreversible loss of capacity during the first cycle, and a material with the composition Li_{0.85}NiO₂ is formed at the end of the first discharge. Lithium deinsertion from this material is highly reversible during subsequent charge–discharge cycles in the potential range from 2.5 to 4.1 V vs. Li/Li⁺. To enhance electrode performance, partial substitution of nickel in LiNiO₂ with elements such as Co, Mn, Mg, Fe, and Al has been carried out. Such doping has been founded to limit the various phase transitions which occur while deinserting lithium ions, and to stabilize the layered structure of LiNiO₂ [130].

Much effort has been devoted to the study of manganese oxides as positive electrode materials. Manganese oxides are very promising materials due to their abundance, environmental compatibility, low cost, favorable charge density, relatively high electronic conductivity, and suitable electrode potentials. Different structures of manganese oxides have been investigated and the best known, and the first to be

Figure 18. Galvanostatic discharge curves at room temperature and at 0.1 mA cm^{-2} for layered cobalt and nickel oxides, and spinel manganese oxide in ethylene carbonate–diethyl carbonate– $\text{LiN}(\text{CF}_3\text{SO}_2)_2$ [134] (by permission of Elsevier Science S.A.: S. Megahed, B. Scrosati, *J. Power Sources* **1994**, *51*, 79–104).

studied, is the cubic spinel LiMn_2O_4 , which is characterized by a three-dimensional array of interconnected voids for the lithium insertion [131]. Layered manganese oxides [132] and tunnel structures [133], with two- and one-dimensional paths for lithium insertion, respectively, have also been investigated.

Manganese oxides with three-dimensional ion paths have two main advantages over the layered structures: the co-insertion of solvent molecules can be avoided for steric reasons and volume expansion–contraction upon lithium insertion–deinsertion is minor in extent. Besides LiNiO_2 and LiCoO_2 , the lithiated spinel LiMn_2O_4 is at present a very popular positive electrode material; Figure 18 compares galvanostatic discharge curves of the three metal oxides [134].

The LiMn_2O_4 spinel structure, shown in Figure 19, can be described as a cubic close-packed oxygen array with the manganese cations occupying one-half of the octahedral interstitial sites and the lithium cations one-eighth of the tetrahedral sites. The interstitial tetrahedral and octahedral spaces in the $[\text{Mn}_2]\text{O}_4$ framework are interconnected to form three-dimensional pathways for Li^+ ion diffusion (10^{-12} – $10^{-14} \text{ m}^2 \text{ s}^{-1}$).

The electrochemical Li^+ deinsertion from LiMn_2O_4 (Eq. (46))

is reversible and proceeds at about 4 V vs. Li/Li^+ via a two-step process involving a phase transition at $\text{Li}_{0.5}\text{Mn}_2\text{O}_4$. In Figure 20 A and B indicate the corresponding

Figure 19. LiMn_2O_4 spinel structure, in which the light gray spheres represent lithium, the dark gray ones the oxygen and the solid areas the manganese.

Figure 20. Typical $\text{Li}_x\text{Mn}_2\text{O}_4$ cyclic voltammetry [111] (by permission of Wiley-VCH Verlag GmbH: M. Winter, J.O. Besenhard, M.E. Spahr, P. Novák, *Adv. Mater.* **1998**, *10*, 725–763).

voltammetric peaks. During charging and discharging in the 4 V potential domain, the unit cell exhibits a minimal contraction over a wide composition range, and this results in the satisfactory rechargeability and cycling stability of LiMn_2O_4 . However, at practical potentials (4.5 V vs. Li/Li^+) it is not possible to extract all the lithium electrochemically to yield $\lambda\text{-MnO}_2$.

The empty sites of LiMn_2O_4 can also insert additional Li^+ at about 3 V vs. Li/Li^+ (peak C in Figure 20).

Table 5. Observed specific capacity delivered over 3 V vs. Li/Li⁺ for different mixed oxides.

Composition	Potential range [V]	Observed specific capacity [Ah kg ⁻¹]
Li ₂ CrMn ₃ O ₈	3.4–5.4	125
Li ₂ FeMn ₃ O ₈	3.0–5.3	125
Li ₂ CoMn ₃ O ₈	3.0–5.3	130
Li ₂ NiMn ₃ O ₈	3.9–4.9	111

Cells based on this process (Eq. (47)) show lower cycling performance with respect to those based on the 4 V process because charge–discharge reactions are accompanied by an asymmetric lattice contraction–expansion of the Li_{1+x}Mn₂O₄ electrode. This lattice distortion mainly results from the Jahn–Teller effect of the Mn³⁺ ion which transforms the crystal symmetry of the spinel oxide [118].

Doped spinel manganese oxides in which Mn³⁺ is substituted by other trivalent cations, e.g., Al³⁺, Fe³⁺, Ni³⁺, Co³⁺, or Cr³⁺, have been also investigated; they display enhanced structural stability but decreased specific capacity as compared with the undoped LiMn₂O₄. These compounds are also classified as high-voltage positive electrode materials because they can operate above 4.5 V vs. Li/Li⁺ (Table 5) [135].

With the intent of realizing electrode material with an electrochemical performance as high as that of Ni and Co oxides but less toxic and expensive, layered manganese oxides have also been investigated [132]. The main problem with these materials is that in the final step of the deinsertion process the layered LiMnO₂ irreversibly transforms into the similar spinel structure, thereby reducing cyclability. Recently, a new synthetic method has been proposed that yields a layered manganese oxide featuring a specific capacity of 150 Ah kg⁻¹ and an O2 structure that is stable during repeated charge and discharge cycles [136].

Among the transition metal oxides, mention should also be made of the vanadium oxides, the most studied as positive electrode materials being V₂O₅, V₆O₁₃, and LiV₃O₈, which insert lithium in the potential domain of 3 V vs. Li/Li⁺. For the vanadium oxides, too, doping and suitable structure have been shown to improve their electrochemical performance, and recently a sol–gel process has yielded high-capacity (500–600 Ah kg⁻¹) materials delivering 500 Wh kg⁻¹ at 4 mA cm⁻² [137].

Negative Insertion Materials

Research has also focused on the study of highly reversible negative lithium insertion materials. Transition metal oxides and chalcogenides, such as MoO₂, WO₂, and TiS₂, if combined with a metal oxide positive electrode material yield cells with low OCV values (ca. 1.5–2 V) [111].

Higher OCV values can be attained with lithium alloys (Figure 16), which are under study as negative insertion electrode materials for their high specific capacity

(1700–2000 Ah L⁻¹) and acceptable Li⁺ mobility at room temperature (5.9×10^{-11} – 5.2×10^{-14} m² s⁻¹). Their major drawback is that the corresponding lithium insertion reaction is associated with large volume changes (typically 100 % for Li_xAl alloys) because the reduction of Li_xM alloys yields M⁻ ions which are considerably larger than neutral M atoms. Furthermore, lithium alloys, having a highly ionic character, are fairly brittle and mechanical stresses related to the volume changes can, as an extreme result, lead to “pulverization” of the electrode, thereby limiting the cycle life [113].

Using alloys with micro-, nano-, or subnanoparticle sizes makes it possible to enhance lithium alloy cyclability. With such morphology, relatively large dimensional changes of the crystallites do not cause particle cracking since the absolute changes in the particle dimensions are small [138].

At present, the most widely used insertion negative electrode materials are carbon-based: they exhibit higher specific capacity and more negative redox potentials than most metal oxides and chalcogenides, and, due to their dimensional stability, they show better cycling performance than lithium alloys [139]. The insertion properties of carbonaceous materials depend on their crystallinity, microstructure, and micromorphology and hundreds of types and qualities of carbons have been investigated, including fullerenes [140] and nanotube carbons [141].

Carbonaceous materials can be classified roughly as graphitic and nongraphitic. Graphitic carbons have a layered structure, although with a number of structural defects differentiating them from the ideal graphite structure of Figure 21(a). They are more commonly an aggregate of graphite crystallites of different dimensions. For instance, the highly oriented pyrolytic graphite consists of large aggregates that are relatively free of defects. Under ambient conditions, graphite inserts a maximum of one lithium atom per six carbon atoms; the specific capacity is 372 Ah kg⁻¹ [126].

Figure 21. a) Schematic drawing of lithiated hexagonal graphite Li_xC₆, and stacking arrangement by Franklin models for b) soft and c) hard carbons [R.E. Franklin, *Proc. Roy. Soc.* **1951**, A209, 196].

Nongraphitic carbonaceous materials do not show a crystallographic order in the *c*-direction. The structure of these carbons is characterized by both amorphous and graphitic areas and consists of two-dimensional ordered graphene sheets which are randomly stacked. It is common to divide the nongraphitic carbons into “soft” (Figure 21b) and “hard” carbons (Figure 21c), as the former (e.g., cokes and carbon black), unlike the latter, can be graphitized by heat treatment. Hard carbons seem to be the better performing with respect to soft and graphitic ones [142].

In practice, Li^+ insertion into carbon is not fully reversible: during the first cycle there is an irreversible capacity loss, while in the subsequent cycles the coulombic efficiency is close to 100 %. The excess charge (irreversible capacity) consumed in the first cycle is generally ascribed to the formation of a passivating film and to corrosion-like reactions of Li_xC_6 . The magnitude of this irreversible capacity depends on the kind of carbonaceous material and on the electrolyte composition [143, 144].

Often, insertion of Li^+ from organic electrolytes into graphitic carbons leads to the insertion of the solvent, which is associated with extreme expansion of the graphite matrix (ca. 150 %) and the deterioration and exfoliation of the graphite. The resulting decrease in charge storage capability can be limited by using ethylene carbonate-based electrolytes. The decomposition compounds, resulting from the reaction of graphite with these electrolytes, form in the early stages of the first reduction a protective film on the electrode surface which limits the extent of solvent co-insertion [145].

Recently, Fujifilm Celtec has proposed new negative electrode materials with excellent electrochemical properties: tin-based amorphous oxides containing elements of groups III, IV, and V, such as boron and phosphorus. These materials show high specific capacity, up to 600 Ah kg^{-1} and 2200 Ah L^{-1} [146].

2.5 Present Status and Future Prospects

At the moment the plastic lithium-ion batteries are at the cutting edge of battery technology and several companies (Panasonic, Sony, Japan Storage, Hitachi Maxell, and Shubila) have marketed them since 1999 in a range of varying sizes, with graphite and LiCoO_2 as negative and positive electrode materials, respectively.

In future magnesium-based rechargeable batteries might prove to be a viable alternative to lithium-based batteries [147]. Despite the fact that the magnesium redox potential is less negative than that of lithium and the Mg equivalent weight is slightly higher than that of lithium, the natural abundance of magnesium, its low cost, and its safety characteristics make it a promising negative electrode material. However, magnesium electrochemistry near or at room temperature is not fully understood and there are few data on Mg-based electrodes (e.g., Mg^{2+} insertion materials): considerable effort is thus needed before a competitive magnesium-based rechargeable battery can be brought to market.

This chapter is not intended as an exhaustive treatment of batteries as such. Rather, it seeks to bring to the fore the wide-ranging importance of one application of electron transfer: batteries. Of no less importance in this connection is the enormous effort of interdisciplinary research needed to develop batteries responsive to scientific advances and technological innovations—research that is strengthened under the pressure of market demand.

3 Principles of Semiconductor-assisted Photocatalysis for Waste Remediation

Marion C. Thurnauer, Tijana Rajh, and Nada M. Dimitrijevic

3.1 Introduction

Semiconductor photocatalysis has proven to be a promising technology for use in the cleanup of water contaminated with hazardous industrial by-products. Particulate semiconductors have proven to be light-harvesting materials and mediators in the photochemical degradation of several environmental contaminants [1–12]. Due to the large oxidation potential of photogenerated holes, oxidative degradation of the most resistant pollutants by photocatalysis can be achieved. Numerous reports of organic pollutant degradation, with mineralization to inorganic products in several cases, have been published [13–16]. Titanium dioxide, in particular, could be the catalyst of choice for a large variety of applications because it is cheap, non-toxic, and has redox properties which are favorable both for oxidation of many organic pollutants and for the reduction of a number of metal ions or organics in aqueous solution.

To date, the primary focus of TiO_2 -assisted photocatalysis studies has been on the destruction of organic pollutants in solutions, using photocatalytic oxidation. Anatase TiO_2 particulates are proven photooxidizers of a variety of organic compounds (phenols, chlorinated phenols, polychlorinated biphenyls (PCBs), dioxins, DDT, surfactants, saturated aliphatic hydrocarbons, *s*-triazine, etc) [17]. Photo-oxidation leads ultimately to complete degradation of these “pollutants”. However, the detailed mechanism of pollutant degradation differs from one pollutant to another. On the other hand, the common feature of the photocatalytic process always involves reactions via surface-trapped electrons and holes. The process occurs under ambient conditions, minimizes or avoids formation of intermediate products, and leads to complete oxidation of the substrates to CO_2 , thus offering a great potential as an industrial technology to detoxify wastewaters [18]. TiO_2 -assisted photocatalysis may also be useful in the removal of certain heavy metals, including mercury, silver, platinum, palladium, rhodium, and gold, via their reduction followed by deposition at the catalyst surface [17, 19, 20, 21].

Although TiO_2 is very effective from an energetic point of view, it is relatively inefficient. The main energy loss in all investigated systems is due to the recombination of charges generated in the illumination of semiconductor particles, which is manifested as relatively low efficiency of pollutant decomposition. Therefore, the main focus of research for application of semiconductor-assisted photocatalysis is to improve separation of charges and at the same time preserve or improve their redox properties. Additionally, large-bandgap semiconductors such as TiO_2 absorb only a fraction of the white light (5 %), and another issue of concern for the optimization of photocatalysts is to sensitize large-bandgap semiconductors in the visible region by dye or ligand adsorption onto large-surface-area metal oxides [22]. Other novel approaches focus on increasing the energy of the photons used for excitation of metal oxides (in the region of γ -, X- or far-UV-radiation) [23].

3.2 Colloidal Semiconductors

Semiconductors are generally crystalline materials which are assembled into arrays of repeating atomic (molecular) units. When similar atoms are brought together to form a crystal the wavefunctions of their electrons begin to overlap. In order to satisfy Pauli's Exclusion Principle, two electrons cannot have the same quantum numbers and therefore more than two electrons cannot occupy a single orbital. As a consequence, if N atoms are packed within the range of interaction, electrons of the same orbital have to occupy $2N$ different states, forming a band of states instead of discrete levels. Overlap of the energy levels occupied by existing electrons results in the formation of the valence band, while the overlap of the unoccupied excited states results in the formation of the empty conduction band. Between these two bands an energy gap is formed in which no electron states are allowed. It is the extent of the energy gap that determines whether a crystalline solid is a metal, a semiconductor, or an insulator. The energy distribution of the state depends strongly on the interatomic distance. The average amount by which the potential energy has dropped is related to the cohesive energy of the crystal. Since the interatomic distance in a crystal is not isotropic but rather varies with crystallographic direction, it can be expected that the banding of the energy states will vary with crystal planes. Allowed energy states have a parabolic dependence in the wave space for wave vector $\mathbf{k} \sim 0$ ([000]); however, additional minima can occur in a specific crystallographic direction (such as [111] or [110]).

3.2.1 Optical Properties of Semiconductors

The fundamental absorption refers to promotion of electrons from the valence to the conduction band. Due to the continuous nature of the energy bands, semiconductors absorb all the light below the threshold wavelength, which is the direct measure of the bandgap (E_g) energy (Eq. (1)).

Figure 1. Schematic presentation of a) direct and b) indirect transitions in semiconductors [24].

$$\lambda_g[\text{nm}] = 1238.9/E_g[\text{eV}] \quad (1)$$

For exact determination of the bandgap energy one has to take into account the dependence of the absorption coefficient on the energy of absorbed photons, which differs for various semiconductors. In the case when the energy minimum of the conduction band and the energy maximum of the valence band occur at the same wave vector k value, typically $k = 0$, the transition is considered allowed and direct (Figure 1a). The transition probability, then, is independent of photon energy. Absorption, expressed in terms of a coefficient $\alpha(h\nu)$, defined as the relative rate of decrease in light intensity $L(h\nu)$ along its propagation path in this case is given by Eq. (2),

$$\alpha[h\nu] \propto (h\nu - E_g)^{1/2} [\text{cm}^{-1}] \quad (2)$$

$h\nu$ and E_g being expressed in electronvolts [24]. The graphical presentation of the square of absorption coefficient vs. photon energy is a straight line whose slope and intercept define the bandgap of the semiconductor.

In some materials, quantum selection rules forbid direct transitions at $k = 0$ but allow direct transition at $k \neq 0$. In this case the transition probability increases with k^2 , and the absorption coefficient has spectral dependence according to Eq. (3).

$$\alpha[h\nu] \propto (h\nu - E_g)^{3/2} [\text{cm}^{-1}] \quad (3)$$

In this case the plot of $\alpha^{2/3}$ vs. photon energy reveals the characteristic parameters of a semiconductor.

When the transition requires a change of momentum, as in anatase TiO_2 , an indirect transition between indirect valleys occurs. As a photon cannot produce a

change in momentum, conservation of momentum occurs via a phonon interaction. Among the broad spectrum of phonons, only those with the required momentum change are usable (longitudinal and transverse acoustic phonons). Each of these phonons has the characteristic energy E_p and can be either emitted or absorbed (Figure 1b). The absorption coefficient is then the sum of absorption coefficients associated with emitted and absorbed phonons (Eq. (4)).

$$\alpha(h\nu) = \alpha_a(h\nu) + \alpha_e(h\nu) \quad (4)$$

The α of each of these processes is proportional to the probability of interacting with phonons (i.e., proportional to a function of the number of phonons $f(T, E_p)$) and density of states:

$$\alpha(h\nu)_{a/e} \propto f(T, E_p)(h\nu - E_g \pm E_p)^2 \quad (5)$$

At very low temperatures, the phonon density is very small and therefore the probability of phonon absorption is also low. In this case one finds that the plot of the square root of α has a linear dependence on $h\nu$. At higher temperatures, however, the linear dependence breaks into two linear parts with different slopes corresponding to the emissive and absorptive processes.

3.2.2 Quantization Effect

When the particle size of the semiconductor crystallites is less than the de Broglie wavelength, depending upon the specific electronic properties of the semiconductor such as the effective masses of electrons and holes, very interesting and important effects become apparent. These effects arise because of the physical confinement of electrons and holes in potential wells defined by the crystallite boundaries. As a consequence, only those orbitals that fulfill the condition of having a node at the crystallite boundaries are allowed, i.e., only those orbitals that have $k = \pm n\pi/R$, where R is the radius of a particle, are allowed. The most general consequence of these boundary conditions is that the energy levels available for electrons and holes in the conduction and valence bands become discrete. They are quantized, rather than continuous [25]. However, the most obvious consequence of the boundaries is that the transition at $k = 0$ becomes forbidden, and this is manifest by an apparent increase in the bandgap of a semiconductor, which is inversely proportional to the values of the effective masses of electrons and holes; the magnitude of this increase is significant only for semiconductors with effective masses $\leq 0.5m_e$. These giant molecules (collective entities of 10^3 – 10^6 atoms) exhibit atom-like, size-dependent properties that are different from the properties of their constituents. Because of the relatively broad distribution of particle sizes in the earlier preparations of colloids, the spectral structure resulting from size-dependent properties was washed out. Various size-selective methods have been developed recently [26] that lead to extremely narrow particle distributions and pronounced structure of the absorption spectra. The optical spectra of spherical quantum dots were previously investigated using size-selective physical methods in order to avoid inhomogeneous line broadening

[27]. The quantization effects that result in a size-selective increase in the bandgap of CdTe are illustrated in Figure 2 [28]. The blue shift of the fundamental absorption edge, i.e., the increase in the effective bandgap with a decrease in particle size, is a direct consequence of the size quantization effect. Also, Figure 2 demonstrates that the oscillator strength of the first excitonic state in strong confinement regions (when $R < \text{Bohr radius}$) follows an inverse cube dependence on the particle diameter (increasing with $1/R^3$) due to the overlap of the electron and hole wavefunctions.

Quantization effects also greatly influence the charge transfer processes. The decrease in particle size results in a shift of the conduction band to the more negative values, and of the valence band to more positive ones. Hence, such ultrafine particles exhibit enhanced photoredox properties compared with the bulk material: the redox processes that cannot occur in a bulk semiconductor particle can be facilitated in quantized particles. On the other hand, an increase in the effective bandgap might lead to decreased stability of such particles, because the position of the cathodic and anodic corrosion potentials might fall between the band edges. It was shown that a shift in the reduction potential of about 1.2 V occurs for quantized CdTe particles, a material with extremely low effective masses of electrons and holes. The enhanced photoredox properties of quantized semiconductor particles was undoubtedly proven when the reduction of water to H_2 was achieved with photogenerated electrons from quantized HgSe [29]. The use of bulk HgSe under the same conditions did not result in hydrogen production.

3.2.3 Space Charge Layer and Band Bending

When a semiconductor is brought into contact with an electrolyte, a migration of charge carriers occurs until the Fermi level of the semiconductor is equilibrated with the chemical potential of the electrolyte [30]. This results in the formation of a space charge layer in the surface region of a semiconductor and a Helmholtz double layer in the electrolyte adjacent to the semiconductor surface. The electrons are transferred in and out of a semiconductor surface depending on the relative position of the initial Fermi level of the dry semiconductor and the electrochemical potential of the electrolyte. In the case when the Fermi level of a dry semiconductor is more negative than the electrochemical potential of the electrolyte (n-type semiconductor; electrons are the majority carriers), the electrons leave the semiconductor, resulting in a shift of the Fermi level toward more positive potentials (Figure 3) [30]. The depletion of the surface region creates a barrier for further transfer of electrons to the electrolyte which is manifest by band bending in the space charge layer. In the opposite case (p-type semiconductors) the Fermi level has a negative shift, causing accumulation of electrons in the space charge region. Photons absorbed in the depletion layer produce electron–hole pairs that separate under the influence of the electric field. This separation of the carriers causes the Fermi level in the semiconductor to return toward its original position, i.e., the energy position before a semiconductor/electrolyte junction was established. The space charge region in the solid is fairly large, approximately 1000 Å, while the Helmholtz double region together with the diffuse Helmholtz layer is 100 Å [31]. However, when the size of a semiconductor approaches the size of the space charge layer, the small particle is

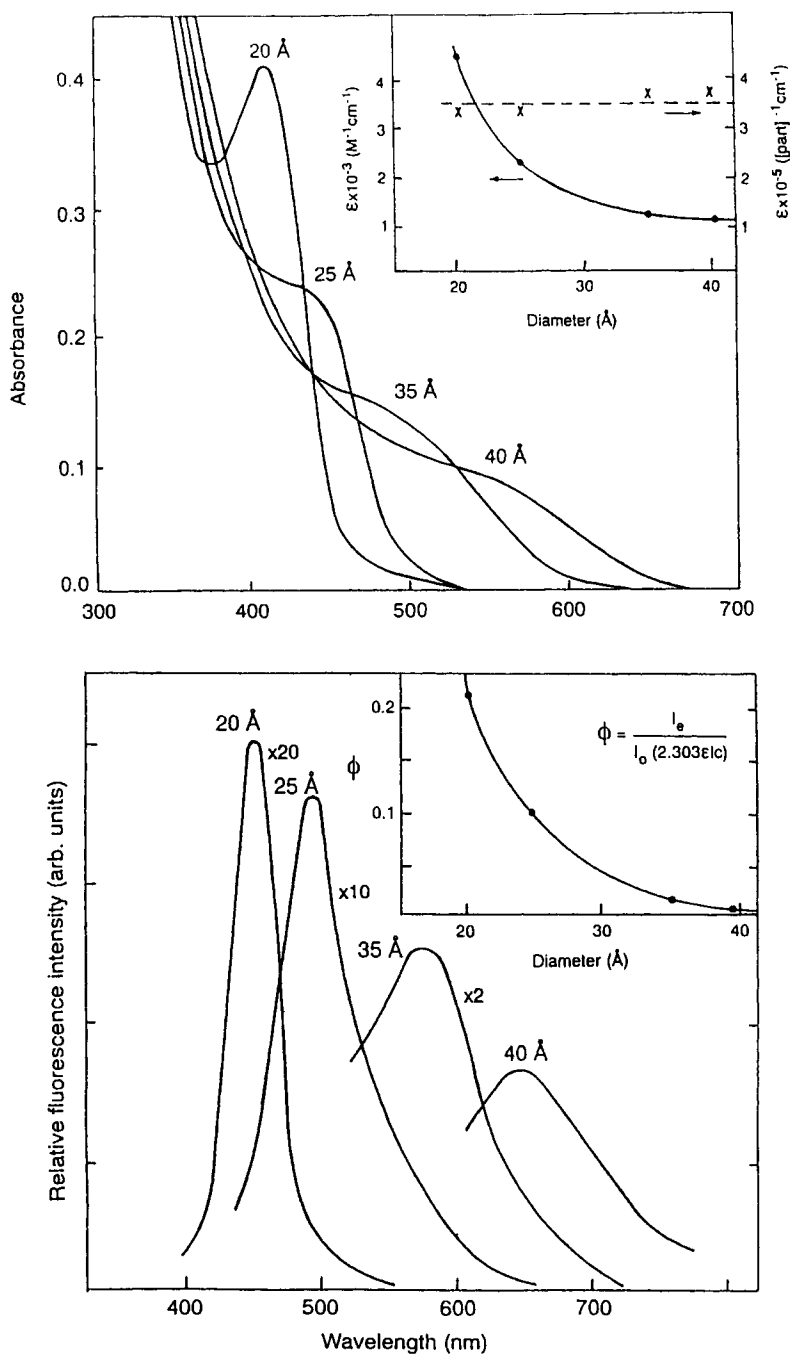

Figure 2. Absorption (top) and emission (bottom) spectra of CdTe with different particle sizes [28]. (Reprinted with permission from T. Rajh, O. I. Micic, A. J. Nozik, *J. Phys. Chem.*, **1993**, 97, 11999. Copyright (2000) American Chemical Society.)

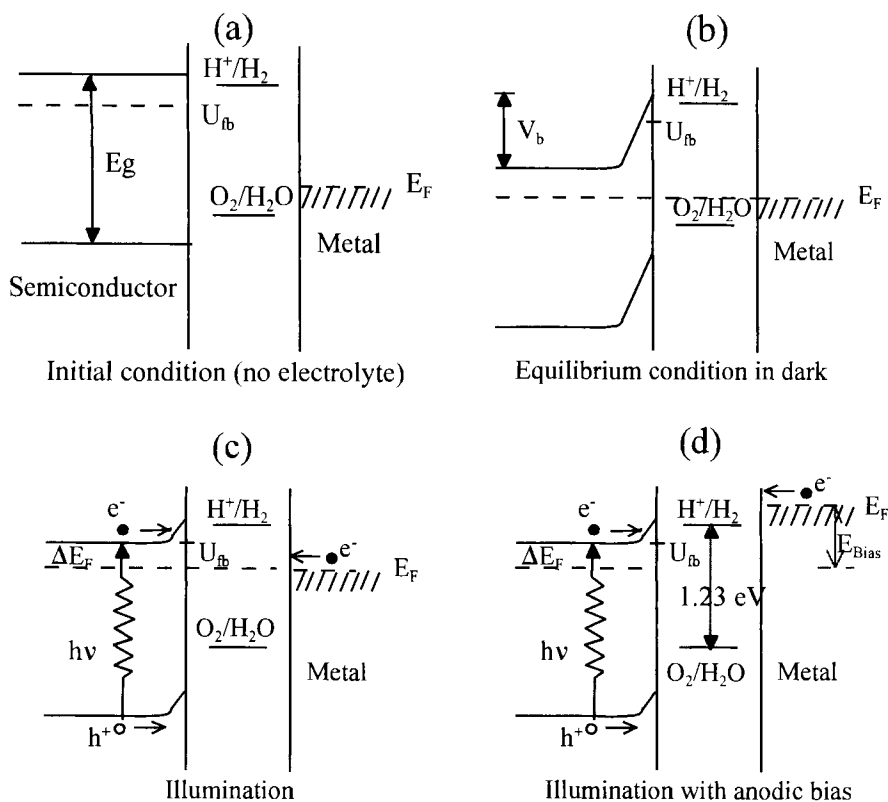

Figure 3. Sequence of energy level diagrams for semiconductor/metal photoelectrolysis cell [30].

depleted almost completely of charge carriers and band bending is negligible. The particles are too small to develop a space charge layer and, in this case, the potential difference resulting from transfer of a charge from a semiconductor to the electrolyte has to drop within the Helmholtz layer (neglecting diffuse layer contributions). As a consequence the position of the band edges of semiconductor particles will shift with the shift in the Fermi level [32]. This has an important consequence because, upon illumination, it allows the negative shift of a conduction band edge of n-type colloidal semiconductors.

3.2.4 Energy Band Structure of TiO_2

Titania particles in the small-particle regime have a tetragonally distorted octahedral anatase structure in which every titanium cation is surrounded by six oxygen atoms in an elongated octahedron geometry (D_{2d}). Due to the resultant crystal field, the 3d levels of Ti^{4+} , which form the conduction band of TiO_2 , are split into $3t_{2g}$ and $3e_g$ sublevels. The unequal length of the six cationic ligand bonds to titanium produces a splitting of the t_{2g} and e_g orbitals into two subsets (Figure 4). Symmetry

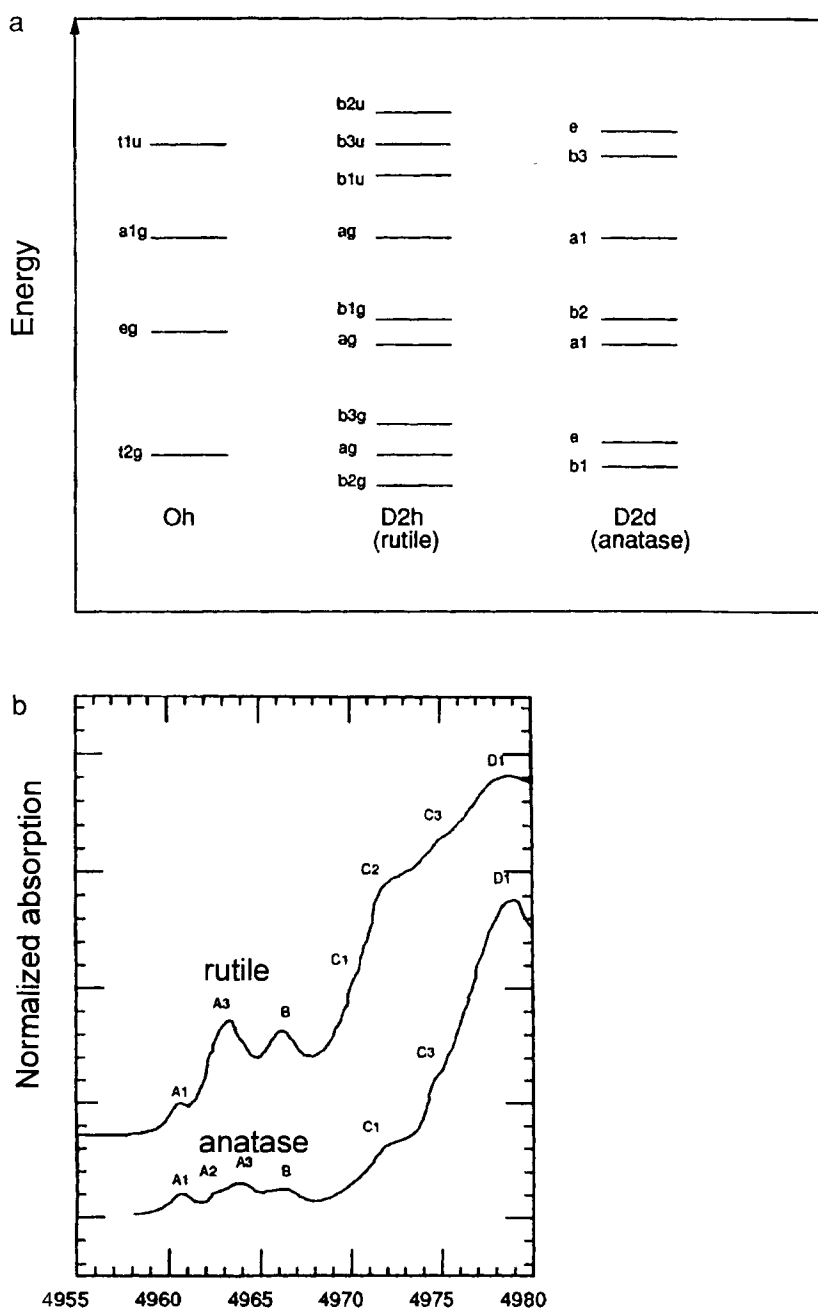

Figure 4. Energy level diagram of the LUMO of a $[\text{TiO}_6]^{8-}$ cluster, a) with O_h , D_{2h} (rutile), and D_{2d} (anatase) symmetry, in conjunction with b) experimental Ti K-edge XANES spectra [33]. (Reprinted with permission from Z. Y. Wu, G. Ouvrard, P. Gressier, C. R. Natoli, *Phys. Rev. B*, **1997**, 55, 10382. Copyright (2000) American Physical Society).

considerations show that the p orbitals of the central Ti atom mix with d orbitals of neighboring Ti atoms and 3d–4p-hybridized sub-bands form the conduction bands of anatase TiO₂. This is exhibited in the X-ray absorption of near-edge structure (XANES) spectrum of TiO₂ [33].

The lowest band of TiO₂ is formed by the b₁ and e sub-bands, which have mainly π character and can overlap in p-type fashion with oxygen p_⊥ orbitals having anionic character. The result is a series of bands in reciprocal space with the maximum of the valence band and minimum of the conduction band in the center of the Brillouin zone (BZ). However, this direct transition $\Gamma_3 \rightarrow \Gamma_1$ is dipole-forbidden (because the HOMO is formed as a mixture of the oxygen p_x and p_y orbitals which correspond to b₁ in *D*_{2d} symmetry, and the LUMO is formed from the lowest of the 3t_g orbitals which correspond to b₁ in *D*_{2d} symmetry). The first allowed transitions are the indirect transitions from the X point at the edge of the BZ to the Γ point in the center of the BZ. The two lowest transitions are X₁ \rightarrow Γ_1 observed with absorption of light with energy 3.026 eV and perpendicular to the crystalline *c* axes, and X₂ \rightarrow Γ_1 observed with absorption of light with energy 3.06 eV and parallel to the crystalline *c* axes. However, the transition $\Gamma_3 \rightarrow X_1$ of 3.19 eV is allowed both with parallel and perpendicular light, accounting for the increase in the transition probability at this energy corresponding to the bandgap energy of anatase TiO₂. The curvature of the bands at these extremes is very small, indicating large effective masses that are determined by different authors to range from 5*m*_e to 30*m*_e [34, 35]. The precise value of the electron effective mass in anatase remains elusive, primarily because of the difficulty of preparation of anatase single crystals. The anatase crystal structure is dominant in the nanocrystalline particle regime, but the rutile structure is the more stable form for bulk crystals. Because of the large effective masses, however, the quantization effect in titania particles is negligible for particle sizes >15 Å, and therefore unimportant. The other significant feature of TiO₂ particles is that the curvature of the wavefunctions on the top of the valence band is larger than the curvature of the bands in the conduction band. This is different from the situation for most semiconductors and indicates that the effective mass of the hole is smaller than the effective mass of the electrons. In the formation of the exciton pairs, a dominant process in small semiconductor particles, the photogenerated holes orbit around the heavier photogenerated electrons. This also suggests that in small titania particles, photogenerated holes would be more likely trapped at the surface of the particle, while electrons would first find trapping sites in the particle interior.

3.3 Basic Mechanisms of Semiconductor-assisted Photocatalysis

3.3.1 Photogeneration of Charge Pairs and Intrinsic Properties of Semiconductors

Semiconductor particles behave as microelectrochemical cells. Absorption of light of energy greater than the bandgap of semiconductor materials generates conduction-

band electrons and valence-band holes. Semiconductor particles are light-harvesting units offering the following distinct advantages in heterogeneous photocatalyzed processes:

- 1) high absorption cross-section of the incident photons;
- 2) fast carrier diffusion; and
- 3) suitable redox levels of the valence and conduction band edges that can yield high efficiencies in converting light energy to useful redox events.

Metal oxides have band structures that are characterized by the existence of an energy gap that separates the highest occupied energy levels (valence band) from the lowest unoccupied energy levels (conduction band). Excitation of, for example, TiO_2 with UV light with energy greater than the bandgap (>3.2 eV) promotes electrons from the valence into the conduction band and generates electron-hole pairs that can be exploited in various processes at the particle interface (Eq. (6)),

where e_{cb}^- is a conduction band (CB) electron and h_{vb}^+ is a valence band (VB) hole. Photogenerated carriers migrate to the particle surface and participate in reduction and oxidation processes at the surface. The thermodynamic limit for the reaction that can be carried out with the photogenerated charge carriers is given by the position of the band edges (i.e., flat band potential). For example, if a reduction of a particular species (A) in the solution is to occur, the conduction band of the semiconductor must be more negative than the relevant redox level, while the oxidation of a particular species (D) by valence band holes requires that the valence band be more positive than the relevant redox potential (Figure 5). Thus, the rela-

Figure 5. Salient features of the electronic structure of semiconductors.

Figure 6. Position of band edges for various semiconductors in electrolytes at pH 7.

tive positions of the band edges in a given semiconductor determine their redox functioning. The threshold energy needed for absorption of light (i.e., the bandgap energy) and the relative positions of the band edges (i.e., the flat band potential) are intrinsic material properties of each semiconductor.

The positions of the valence (VB) and conduction bands (CB) vs. vacuum of the various metal oxides which can be used for removal of pollutants are shown in Figure 6. For example, at pH 7, the potential of conduction band electrons of TiO₂ is -0.54 V (vs. NHE) and that of valence band holes is $+2.7$ V. All redox couples with the standard redox potential more positive than that of the CB electrons and more negative than that of the VB holes can, in principle, be reduced and oxidized respectively on the colloid surface.

In single-crystal electrodes the electric field in the depletion layer of the semiconductor separates the charges and decreases the probability of charge-pair recombination [30]. However, in small-particle colloids such a depletion layer does not exist due to the nanometer particle size, and there is no electrical field to separate the charges [36]. Due to the large recombination rate in small-particle colloids, the lifetime of charged pairs is very short, and only very fast reactions with adsorbed species can lead to efficient charge separation. In order to facilitate chemical pro-

cesses, rapid recombination of the charges must be prevented by removal of one or both of the charge carriers from the regions where they are formed.

3.3.2 Charge Pair Separation and Charge Carrier Trapping

Semiconductor particles have small sizes and their photoelectrochemical properties may not be the same as those of large bulk material. The particle diameter can be smaller than the thickness of the space charge layer and in that case the details of charge separation may not be the same as in a compact semiconductor electrode. The particles also have a large surface-to-bulk ratio and surface states are therefore especially important in the interpretation of the photoelectrochemical behavior of particulate semiconductors. Therefore, once the electron-hole pairs are generated in the conduction/valence bands, the loss of excess energy through their localization on the trapping sites is more favorable than the radiative, band-to-band, recombination process [37].

Electrons and holes that are generated in particulate semiconductors are localized at different defect sites on the surface and in the lattice of the particles. Electron paramagnetic resonance (EPR) results have shown that electrons are trapped as two reduced metal centers—Ti(III) sites—coordinated either [38, 39] 1) with anatase lattice oxygen atoms only, or 2) with OH or H₂O; the holes are trapped as oxygen-centered radicals covalently linked to surface titanium atoms [40] (Figure 7). This is summarized by Eqs. (7)–(9).

Figure 7. Salient features of the electronic structure of trapping sites in nanocrystalline anatase particles.

The trapping sites are deep and the photogenerated carriers lose a significant amount of energy in the trapping process, but do not attain a large charge separation distance. The position of the Fermi level in small-particle colloids (50 Å) was determined by pulse radiolysis to be slightly more negative (100 mV, shown in Figure 8a) than the flat band potential of single-crystal electrodes [41]. The difference is the consequence of the presence of negative charges on the large surface of small-particle colloids. Using EPR, the relative positions of the levels for electron-trapping sites was found to be the following: $-e_{cb}^- > -\text{Ti(III)}_{\text{latt}} > -\text{Ti(III)}_{\text{surf}}\text{OH}$. The surface trapping sites $-\text{Ti(III)}_{\text{surf}}\text{OH}$ were shown to have optical absorptions peaking at $\lambda_{\text{max}} = 600$ nm [41]. The position of the absorption maximum indicates that the surface electron-trapping sites are deep traps. Therefore, the photogenerated electrons lose significant reducing power in the surface localization process and could not be used effectively for the reduction of species present in the electrolyte.

Similarly, the position of the hole-trapping site was determined to be deep into the mid-gap region, ranging from 2.0 V at pH 3 to 1.5 V at pH 10 vs. NHE (Figure 8b) [42]. Compared with the oxidative power of valence band holes of 2.9 V at pH 3 and 2.5 V at pH 10, one can see an energy loss of almost 1 eV upon trapping. Nevertheless, the oxidative power of trapped holes is still extremely high and can decompose the majority of organic compounds in wastewaters. The only disadvantage is that oxidation is nonselective.

3.3.3 Charge Carrier Recombination and Interfacial Electron Transfer

After they are trapped, charge carriers can either undergo interfacial charge transfer in which they react with redox couples in the surrounding medium, or they can experience electrostatic attraction and recombine. Because the particle diameter is typically smaller than the thickness of the space charge layer, there is no band bending in small particle colloids. Thus, there is no electrostatic field that would drive charge pair separation, and charge pairs are mainly consumed in radiative and nonradiative recombination processes. Different recombination pathways are shown schematically in Figure 7. Most of the recombination processes are nonradiative in TiO_2 , and mainly involve trapped electrons and holes:

Unlike the single-crystal electrodes in which band bending allows efficient charge

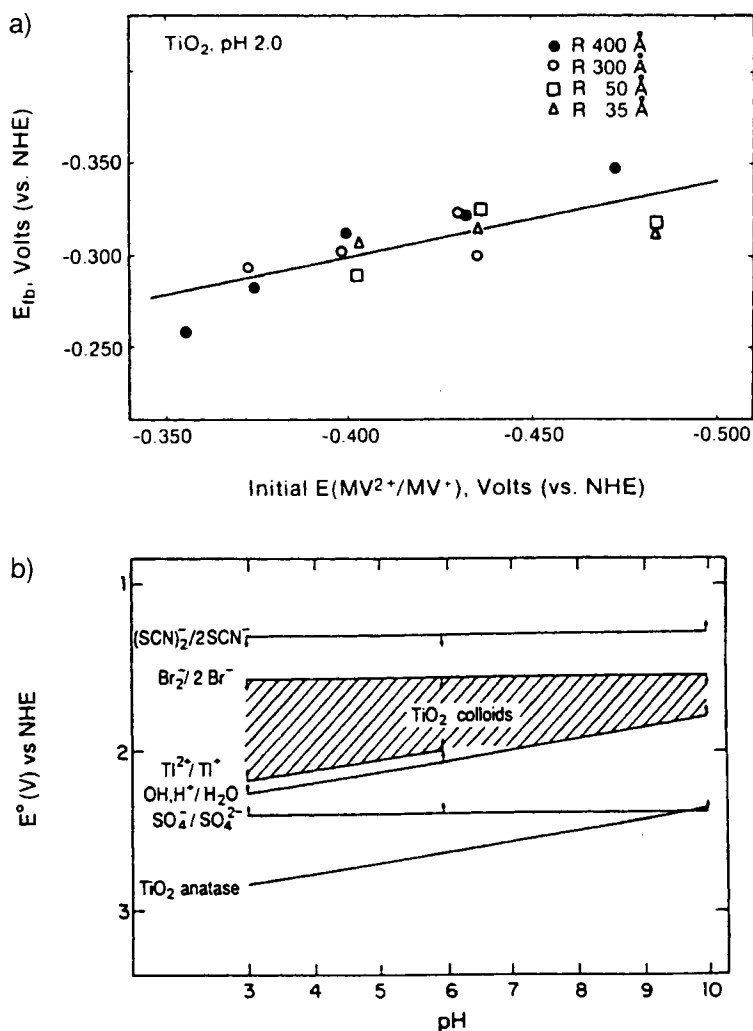

Figure 8. a) Energy level position in nanocrystalline TiO_2 particles of flat band [41]. (Reprinted with permission from N. M. Dimitrijevic, D. Savic, O. I. Micic, A. J. Nozik, *J. Phys. Chem.*, **1984**, 88, 4278. Copyright (2000) American Chemical Society). b) Energy level position of surface-trapped holes [42]. (From O. I. Micic, T. Rajh, M. V. Comor, in *Electrochemistry in Colloids and Dispersions*. (Eds.: R. A. Mackay, J. Texter), VCH, New York, **1992**, p. 457. Reprinted by permission of John Wiley & Sons, Inc.).

separation beyond their correlation distance, in small-particle colloids electron transfer is efficient only if electron donor or acceptor molecules are strongly associated with the particle surface. The overall quantum efficiency for interfacial charge transfer is determined by two critical processes. They are the competition between the free carrier recombination and trapping (time scale of picoseconds) [43]

followed by the competition between trapped carrier recombination and interfacial charge transfer (time scale of microseconds) [44]. Due to the short lifetime of charge carriers, one or both of those formed during illumination have to be removed from the particle before their recombination. This situation can be achieved only by fast reaction with adsorbed species.

3.3.4 Nature of Trapping Sites

In order to be able to block the surface trapping sites and convert them into coupling agents for interfacial electron transfer, one has to determine the nature of trapping sites at the molecular level. It was suggested that interfacial electron transfer in TiO_2 colloids occurs via surface Ti atoms which are coordinated with solvent molecules [45]. Meanwhile, the hole transfer occurs via surface oxygen atoms covalently linked to surface titanium atoms [40]. Both trapping sites have been investigated by several spectroscopic techniques, such as flash photolysis [43, 46], pulse radiolysis [41, 42, 47], and EPR techniques [38, 39, 40].

The coordination environment of surface Ti atoms of particles of different sizes was studied using XANES [48]. Reduction of the particle size was found to result in changes in the relative intensities and peak positions in the pre-edge features of the Ti K-edge spectrum (Figure 9). The XANES results suggest that coordination of Ti surface atoms changes from six-coordinate (octahedral) in 500 Å to pentacoordinate (square pyramidal) in small-particle colloids. The changes in the coordination environment are observed for particle sizes below 200 Å and this distortion of the bond length accounts for the large curvature of small particles and converts surface sites into more reactive “corner defects”.

Detailed investigation of excess holes in TiO_2 colloids reveals the nature of the hole-trapping sites. While pulse radiolysis enables investigation of the kinetics of both hole trapping and reactions of trapped holes, EPR spectroscopy provides a probe of the molecular environment of paramagnetic intermediates on oxidized surfaces. Analysis shows that $\text{O}^{\bullet-}$ radicals that are covalently bound to surface Ti atoms are the primary traps of photogenerated holes. This analysis gives direct evidence that photoinduced holes are located at the colloid surface (nonaxial symmetry) and are not ejected as free hydroxyl radicals (Figure 10). However, Sunada and Heller [49] have reported that upon surface modification with strongly coupled alkane silane modifiers, these deep trapping sites are removed and the formation of highly reactive hydroxyl radicals was observed.

3.3.5 Adsorption

The strong correlation between degradation rates and concentrations of organic pollutants adsorbed on the surface [11, 50] implies that photomineralization requires adsorption. In general, the kinetics of photodegradation of organic substrates sensitized by TiO_2 on steady-state illumination fits a Langmuir–Hinshelwood adsorption kinetic scheme, i.e. Eq. (13),

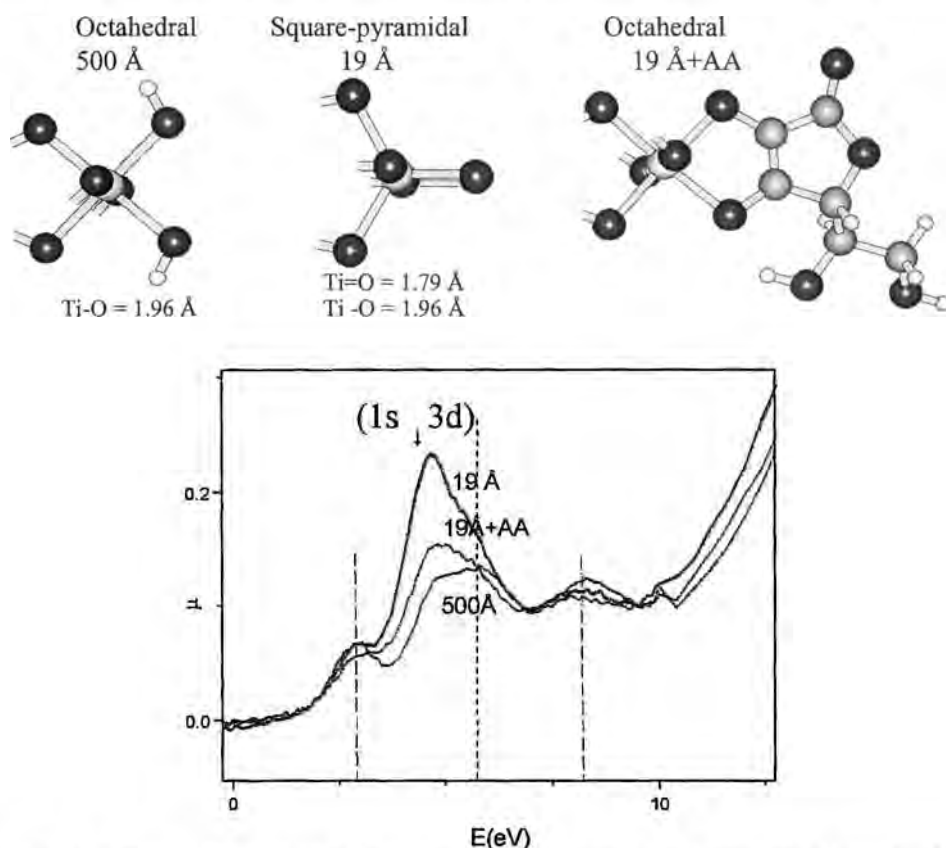

Figure 9. Schematic presentation of the coordination environment of different particle sizes of TiO₂ derived from investigation of XANES studies of the pre-edge Ti K-edge structure [63]. (Reprinted with permission from T. Rajh, J. Nedelkovic, L. X. Chen, O. Poluektov, M. C. Thurnauer, *J. Phys. Chem. B*, **1999**, *103*, 3515–3519. Copyright (2000) American Chemical Society.)

$$R_i = -\frac{d[S]_i}{dt} = \frac{k_s K_s [S]_i}{1 + K_s [S]_i} \quad (13)$$

where R_i is the initial rate of substrate removal, $[S]_i$ is the initial concentration of the organic substrate, K_s is the Langmuir adsorption constant of species S on the surface of TiO₂, and k_s is a proportionality constant which provides a measure of the intrinsic reactivity of the photoactivated surface with S. It was found that the value of K_s is not exactly equivalent to the Langmuir adsorption isotherm for the semiconductor in the dark; additionally, it was found to be dependent on the rate of light absorption (I) as well as the concentration of electron acceptor (commonly O₂). Detailed analysis of the adsorption kinetics on TiO₂ was presented by Mills and Le Hunte [51]. The overall quantum efficiency of photodegradation is defined

Figure 10. EPR spectra of TiO_2 colloids under illumination with a 308 nm excimer laser [40]. (Reprinted with permission from O. I. Micic, Y. Zhang, K. R. Cromack, A. D. Trifunac, M. C. Thurnauer, *J. Phys. Chem.*, **1993**, 97, 7277. Copyright (2000) American Chemical Society.)

by Eq. (14)

$$\Phi = \frac{\text{rate of reaction}(R_i)}{\text{rate of photon absorption}(I)} \quad (14)$$

and is therefore directly proportional to the adsorption.

The main conclusion from the above measurements is that a critical step in photodegradation is adsorption of the organic substrate on the surface. Therefore the parameters that control photodegradation are directly related to the parameters that govern adsorption processes, and include van der Waals forces, dipole–dipole interaction, ion-exchange, hydrogen bonding, hydrophobic interactions, π – π interactions, and donor–acceptor interactions.

3.4 Enhanced Charge Separation: Route for Efficient Photodegradation

3.4.1 Metallization of Semiconductor Particles

The addition of metal particles to semiconductor photocatalysts increases the photocatalytic activity of these systems because metals efficiently scavenge photo-generated electrons [52]. In fact, metallized semiconductors have been utilized as solar-absorbing coatings and as photocatalysts in the remediation of groundwater contaminants [52, 53]. There have been several photocatalytic studies of platinized titanium dioxide. In solution, Pt/TiO₂ is found to increase the photodecomposition rate of several organic compounds compared with that in the presence of neat TiO₂ [54–58].

Anpo et al. [59] studied Pt-loaded TiO₂ encapsulated in Y-zeolites, and found that TiO₂ photoluminescence is efficiently quenched in the presence of Pt. They have also found efficient electron transfer from the electrons trapped on TiO₂ particles (Ti³⁺) to platinum metal islands, thus promoting charge separation. Enhanced charge separation prevents the reaction between carbon radicals and OH radicals formed on different sites, this promotes the reaction between the carbon radicals and H atoms formed on the Pt metal resulting in formation of CH₄.

Illumination of metal-coated semiconductor particles leads to the accumulation of trapped electrons. Islands of noble metals (Pt, Rh, and Pd) on the surface of particles have higher electron affinity and therefore upon charge pair formation electrons are transferred from the semiconductor particle onto the metal islands. Due to the decreased recombination rate and high electron affinity of noble metals, more than one electron can be stored on metallized particles. Therefore, metal-coated particles can be used for subsequent simultaneous injection of multiple charges, and the reduction of compounds that cannot proceed via a one-electron reduction process. In these processes the crucial parameter that governs charge separation processes is the coupling between semiconductor particles and the metal

islands. Thus a good quality interface, which results in the overlapping of Fermi levels between semiconductor and metal, has to be obtained using photodeposition processes [60].

3.4.2 Surface Modification

The approach that constructively uses surface defect sites and converts them into selective coupling agents tailored for specific bindings of photodegradable substrates is based on surface modification. Photogenerated electrons lose significant energy in the trapping processes at the surface and could not be used effectively for redox chemistry. By blocking the defect sites with appropriate surface modifiers one can enhance the redox properties of photogenerated charges, and at the same time enhance the rate of photodegradation by enhancing the adsorption, i.e., local concentration, of pollutants on the particle surface. The latter will also affect the Fermi level of the metal oxide colloids [61].

Metal oxide colloids have been effectively coupled with multifunctional ligands containing carboxyl groups that bind to the surface of nanoparticles [39]. One can rationally design optimal photocatalysts by tailoring other functional groups for selective adsorption of specific pollutants. For example, extensive work on surface modification for removal of heavy metal ions has recently been performed [62]. The surface of colloidal TiO_2 was modified with a series of bidentate and tridentate organic compounds that have mercapto, carboxyl and amino groups in different relative positions, along with attached hydrocarbon chains of varying lengths.

Analysis of the structural and redox properties of surface-modified TiO_2 colloidal particles together with the dynamics of their photochemistry has indicated principles for the design of an optimal surface modifier for the reduction of heavy metal ions such as lead or cadmium. It was found that the surface modifier must contain a carboxyl group to bind to the colloid surface and at the same time to bind Pb^{2+} and Cd^{2+} ions. A mercapto group that is in an α position relative to a carboxyl group enhances adsorption of both surface modifier and heavy metals to small-particle TiO_2 colloids. The surface modifier must have a hole trap that enhances photo-generated charge-pair separation distances. In these systems, side hydrocarbon groups such as the $-\text{CH}_3$ group in thiolactic acid provide a trapping site for holes. In principle, the aliphatic group can be extended for enhanced charge separation and for the design of the system in which the hydrophobic aliphatic or aromatic part of a surface modifier is to be used selectively for the oxidation of organic compounds.

It was found that surface derivatives modify the redox properties of TiO_2 particles if a surface modifier is an electron-donating species, and that the crucial parameter for effective removal of heavy metal ions is the trade-off between enhanced redox properties of TiO_2 by surface modification and the enhanced redox potential of chelated metal ions. Surface modification can lead to the appearance of a charge transfer complex with small-particle TiO_2 colloids that have an optical absorption threshold at ~ 730 nm. The red shift of the optical absorption provides improved optical properties for use of visible light, i.e., for solar energy conversion [63].

3.4.3 Dye Sensitization

Another aspect of surface modification of semiconductor particles is the extension of their photoresponse toward the visible region. The photocatalytic activity of TiO_2 is limited only to the UV region, and hence solar energy cannot be effectively harvested. Dye sensitization of TiO_2 extends the light absorption and conversion capacity of TiO_2 to the visible spectral region. This is often achieved by attaching sensitizing molecules by direct adsorption or covalent linkage to the particle surface. Several dyes, exhibiting high absorptivity in the visible region, such as porphyrins, ruthenium(II) trisbipyridine, rhodamine, cyanines, and metal phthalocyanines, have been used as sensitizers for TiO_2 [64–68]. The sensitization is achieved by excitation of the dye followed by charge injection from the dye into the conduction band of the semiconductor (Eqs. (15) and (16)).

Because the singlet excited state of a dye is short-lived, it is essential to adsorb these dyes on the particle surface with strong chemical coupling so that electron transfer can occur within the lifetime of the singlet excited state. Coupling of dyes to the TiO_2 surface plays a critical role in achieving fast forward electron transfer and slow back reaction. For example, enhanced degradation of organic pollutants was found for TiO_2 modified with iron(III) phthalocyanines as compared with unmodified TiO_2 . The mechanism is attributed to the cooperative functions of the two components of the photocatalyst (dye and TiO_2). One of the suggested mechanisms of mineralization of organic compounds in the presence of phthalocyanines involves metal–oxene and metal–peroxo types of intermediates that act as the reactive species. Another possibility is that ligation enables enhanced concentration of organic pollutants on the semiconductor surface, which in turn enhances the rate of pollutant destruction.

3.5 Radiation-induced Catalysis on Semiconductor Surfaces

Metal oxides such as SiO_2 and Al_2O_3 have large bandgaps (9.0 and 7.0 eV, respectively) and require high-energy excitation to produce charge separation. Interaction of ionizing radiation with metal oxide semiconductors and dielectrics has been the subject of a number of studies [69, 70] and was found to result in electron excitation from the highest occupied level (valence band) to the lowest unoccupied level (conduction band). Primarily, interaction of ionizing radiation with solids gives rise to energy transfer to the solid medium through inelastic collisions that result in generation of secondary electrons which lose their energy in further collisions with atoms of the solid medium and create a chain formation of radical pairs (Figure

Figure 11. Salient features of the electronic structure of semiconductors under ionizing radiation.

11). These radicals have extremely high potential energy and are able to react non-selectively with adsorbed species. Large radiation doses (>10 kGy) produce atom displacements in the crystal lattice, whereas at lower doses (<100 Gy) adsorbed species are degraded by transfer of the energy initially absorbed by the solid to the adsorbate.

Excitation of TiO_2 particles with ionizing radiation is equivalent to their photo-excitation [69] and generates electron-hole (e^-/h^+) pairs that can be exploited in various processes at the particle interface (Eq. (17)):

The generated carriers migrate to the semiconductor/solution interface where they can oxidize/reduce molecules in solution (Figure 11). The process is analogous to photocatalysis and all the parameters that determine efficient degradation of adsorbed organic pollutants in photocatalysis are present in radiation-induced catalysis. As the relative position of the band edges in a given semiconductor determines their redox functioning, the advantage of radiation-induced catalysis is in the use of large-bandgap semiconductors with thermodynamically very powerful conduction band electrons and valence band holes.

Alumina and silica with high surface areas are among the most examined catalysts [23]. Trapping of free charge carriers has led to the observation of surface-trapped electrons and holes in hydroxylated and in dehydroxylated SiO_2 . Trapping of conduction band electrons results in different trapping sites, depending on the conditions of the surface. Pre-existing defects such as peroxy radicals result in long-lived radicals. However, hydroxylation of the surface introduces short-lived color centers (Eq. (18)).

It has been shown that these visible color centers catalyze chemical reactions [71]. It was recently demonstrated that absorption of ionizing radiation by 22 nm SiO_2 particles suspended in aqueous solutions results in the appearance of hydrated electrons [72], but the holes generated in the particles do not cross the particle/water interface to generate OH radicals [73]. The radiation-induced reductive catalytic degradation of hexachlorobenzene (HCB) adsorbed on alumina colloids was also recently demonstrated [74]. These studies suggest that charge separation and accumulation necessary for the occurrence of multielectron transfer reactions is achievable using high-energy radiation (such as γ -rays or MeV-energy electrons) in the presence of large-bandgap semiconductors.

3.6 Summary

Photoinduced degradation of pollutants is based on the unique properties of anatase TiO_2 and the semiconductor/electrolyte junction. The energetics and kinetics of photoinduced charge transfer reactions across the semiconductor/electrolyte interface are parameters that define the efficiency of photochemical degradation of environmental contaminants. The major advantage of semiconductor-assisted photocatalytic degradation is the great ease with which the semiconductor/electrolyte junction is formed. The semiconductor is simply immersed in the electrolyte, and therefore very small, nanocrystalline particles with extremely large surface areas can be used. This is of significant importance because all previous studies indicate that the parameters that control photodegradation are directly related to the parameters that govern the adsorption processes. However, the main energy loss in all the systems investigated is due to the recombination of charges generated in the illumination of semiconductor particles, which is manifest as a relatively low efficiency of pollutant decomposition. Therefore, the main focus of this review was to understand and discuss the parameters that control charge separation efficiency, and to discuss strategies for improving the overall quantum efficiency of photoassisted degradation of pollutants.
